DEFENDERS OF WILDLIFE
PRAIRIE DOG COALITION
THE HUMANE SOCIETY OF THE UNITED STATES
WWF

May 20, 2019

Russell Bacon, Forest Supervisor
Monique Nelson, Interdisciplinary Team Leader
Medicine Bow-Routt National Forests and Thunder Basin National Grassland
2468 Jackson Street
Laramie, Wyoming 82070

Dear Mr. Bacon and Ms. Nelson:

Please accept the following scoping comments on behalf of Defenders of Wildlife, Prairie Dog Coalition of the Humane Society of the United States, and World Wildlife Fund on the proposed amendment to the Thunder Basin National Grassland Land and Resource Management Plan (LRMP) of 2001, as amended. The Forest Service initiated a public scoping comment period on April 18, 2019 with a notice of intent (84 Fed. Reg. 16240). We have reviewed the Proposed Action and all supporting materials made available by the Forest Service and have provided what we hope are helpful recommendations and supporting information to be incorporated into the public record.

We submit these comments and associated information in the spirit of continued collaboration with the Forest Service and ask that you please address them carefully as you progress through the amendment planning process. Each of the undersigned organizations has dedicated a substantial amount of time and resources to promote the protection and recovery of the Grassland's wildlife, while respecting the Forest Service's multiple use mandate. Our organizations offer considerable expertise on relevant subjects to the proposed amendment, including black-tailed prairie dog and associated species conservation, black-footed ferret recovery, and national forest and grassland management planning.

Defenders of Wildlife. Defenders is a national non-profit conservation organization founded in 1947 dedicated to the protection of all native animals and plants in their natural communities. This includes the prairie dog ecosystem of North America's Great Plains, a focus of ours for many decades. Defenders is a member of the U.S. Fish and Wildlife Service's Black-footed Ferret Recovery Implementation Team and has been active in black-footed ferret recovery since the species was rediscovered in 1981. Current and former staff have published scientific articles on prairie dogs and black-footed ferrets, coauthored the original black-footed ferret recovery plan, and have been involved in Thunder Basin National Grassland management planning and project implementation since scoping began for the 2001 LRMP. We also have significant expertise on the 2012 Planning Rule. We submit these comments on behalf of our more than 1.8 million members and supporters nationwide, including about 3,000 in Wyoming.

Prairie Dog Coalition of the Humane Society of the United States. The Prairie Dog Coalition is committed keeping prairie dogs on the landscape in key conservation areas. We collaborate with other non-profit organizations, agencies, landowners, concerned citizens, and scientists dedicated to the protection of prairie dogs and advancing stronger management plans for the prairie dog ecosystem. To this end, we have aided in the facilitation of the Forest Service's black-tailed prairie dog management plan for the

Thunder Basin National Grassland since 2008. The PDC promotes and conducts conservation projects, advocates for non-lethal management practices and provides educational and outreach resources that advance prairie dog protection and recovery. On the Grassland, we currently collaborate with landowners, the Thunder Basin Prairie Ecosystem Association, Converse County Weed and Pest, and the Forest Service in a pilot vegetative barrier, an economic study analyzing how much it costs a private landowner to provide prairie dog habitat on a productive ranch, and have provided translocation and sylvatic plague management on the ground for nearly a decade.

<u>World Wildlife Fund</u>. As the world's leading conservation organization, WWF works in 100 countries and is supported by more than one million members in the United States and close to five million globally. WWF's unique way of working combines global reach with a foundation in science, involves action at every level from local to global, and ensures the delivery of innovative solutions that meet the needs of both people and nature. Our Northern Great Plains program was established in 2002 to sustain and enhance biodiversity and restore endangered and flagship species throughout the Northern Great Plains. WWF is a member of the U.S. Fish and Wildlife Service's Black-footed Ferret Recovery Implementation Team and seek to fully recover the black-footed ferret and remove it from the Federal List of Endangered and Threatened Wildlife. Since 2010, we have served in partnership with the Forest Service and associated stakeholders on the Thunder Basin National Grassland to help achieve conservation objectives related to the LRMP. We remain committed to this collaborative effort and to transforming human-wildlife conflict to create sustainable solutions for people and wildlife.

We look forward to continuing to work with you as the Grassland's latest amendment process moves forward. Thank you for considering these comments. If you have questions, please do not hesitate to contact us to discuss them.

Sincerely,

Lauren McCain

Scoping Comments on the Proposed Amendment to the Thunder Basin National Grassland Management Plan

Defenders of Wildlife
Prairie Dog Coalition of the Humane Society of the United States
World Wildlife Fund
May 20, 2019

I. Executive Summary

Thunder Basin National Grassland is one of the most important places in North America for the prairie dog ecosystem and the many species that depend on black-tailed prairie dogs and the habitat they create, including the endangered black-footed ferret. Now, U.S. Forest Service leadership is proposing to amend the National Grassland's Management Plan to eliminate critical safeguards and allow poisoning and shooting of prairie dogs across the entire Grassland. This significant management change will undermine wildlife conservation and preclude recovery of the black-footed ferret, among the first species listed under the U.S. Endangered Species Act. Adopting and implementing the proposed amendment will likely violate the National Forest Management Act, the Endangered Species Act, and possibly other laws. We oppose the proposed amendment.

The Forest Service alleges to be seeking a "better balance" between prairie dog conservation and other grassland uses. Thunder Basin's Management Plan has already been amended for this purpose, and the last change resulted from compromises made by all stakeholders, including ranchers, conservation groups, and government entities, agreeing to tradeoffs in its development. The current plan has not been adequately implemented in recent years to address the concerns of ranchers regarding prairie dog expansion into areas near private lands or the concerns of conservationists regarding maintaining and protecting prairie dog colonies. Rather than address the problem of inadequate implementation of the current plan, the Forest Service is appearing to undercut years of compromise meant to address conflicts regarding prairie dog management. The Grassland is federal land that belongs to all Americans, and Forest Service officials are required to serve a strong and abiding public interest in conserving natural landscapes and native wildlife as an important part of its multiple use mandate.

The current Management Plan largely protects prairie dogs from poisoning and shooting in Management Area 3.63, an area specifically designated to maintain at least 18,000 acres of prairie dog colonies to support a viable population of black-footed ferrets and conserve other associated species. The "3.63 area" has been managed by the Forest Service as a future ferret reintroduction site since at least 1985. The area is one of the very few places remaining with the ecological potential to sustain 100 breeding adult ferrets, a requirement for ferret recovery. In fact, the U.S. Fish and Wildlife Service has claimed that Thunder Basin "may well be the best existing site across the species' range in 12 western states, Mexico, and Canada that could significantly contribute to [the ferret's] recovery at the present time."[1]

---

[1] United States Department of Interior, U.S. Fish and Wildlife Service. 2017. Letter to Mr. Brian Ferebee (Regional Forester, U.S. Forest Service, Rocky Mountain Region) from Ms. Noreen E. Walsh (Regional Director, U.S. Fish and Wildlife Service, Mountain-Prairie Region). May 30.

The proposed amendment would eliminate the Management Area 3.63 designation, comprising 44,426 acres (less than 10%) of the Grassland. The new proposal would create a Management Area 3.67 to emphasize rangelands with short-statured vegetation that manages prairie dog colonies “toward a target of 10,000 acres” (Scoping Document: 11) to support prairie dog associated species yet enables the Forest Service to lethally control prairie dogs if their total area exceeds 7,500 acres in this same area. Keeping prairie dog colonies small, at low densities, and isolated from each other are elements of the proposed management approach, which is certain to increase management costs considerably and conflict with the needs of imperiled prairie dog associated species.

Scientists consider prairie dogs “keystone species” and “ecosystem engineers,” and the Forest Service’s proposal could harm over 100 native vertebrate species and a host of invertebrates that benefit from prairie dogs and their colonies. Since the late 1800s, black-tailed prairie dogs have lost over 98% of the territory they once occupied across the Great Plains. Poisoning, often subsidized by the federal government, significantly contributed to this decline. In the early 1900s, humans inadvertently introduced sylvatic plague, which is an exotic disease that decimates small mammal populations, including prairie dogs. The combined threats of poisoning and plague, and to some extent shooting, have led to downward population trends and the imperilment of prairie dogs along with associated species such as mountain plovers, burrowing owls, swift foxes, ferruginous hawks, and black-footed ferrets. The loss of prairie dogs has been particularly disastrous for black-footed ferrets, which only live in prairie dog colonies and were likely extirpated from the Grassland by the 1980s.

The Forest Service may amend a national forest or grassland management plan if ecological conditions or other significant changes have occurred. However, the Forest Service’s amendment proposal is inappropriate for existing conditions on the Grassland. The Forest Service has claimed active prairie dog colony area expanded to 48,000 acres on federal lands within and near Management Area 3.63 between 2015 and 2017, and the agency appears to be framing this expansion as the change the amendment is meant to address. During this time, the 3.63 area contained its largest known occupancy of burrowing owls, mountain plovers, ferruginous hawks, and swift foxes. Then, a sylvatic plague epizootic in 2017 reduced prairie dog colonies on federal lands within and near Management Area 3.63 to approximately 600 acres, a level which is far below the National Grassland’s ability to sustain viable populations of many associated species by any measure. This Grassland is in crisis, not from a need to increase the ability to eliminate prairie dogs but from a need to take active measures already outlined in the current plan to simultaneously restore prairie dog occupancy and minimize conflicts with adjacent landowners.

Ironically, during the Forest Service’s scoping comment period for the amendment, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services issued its milestone report on biodiversity and ecosystem services. Roughly one million species are currently at risk of extinction—some possibly within the next 10 years. Now more than ever the Forest Service needs to lead the way in providing critical habitat for prairie dogs and the numerous wildlife species associated with their presence on Wyoming’s Thunder Basin National Grassland. The Forest Service can contribute to the recovery of the black-footed ferret and simultaneously honor its multiple use mandate, including livestock grazing, as they are not mutually exclusive.

In lieu of substantially reducing prairie dog populations and eliminating the Management Area 3.63 emphasis on black-footed ferret reintroduction to address the concerns of neighboring landowners and livestock permittees, the Forest Service should focus on improving collaborative efforts that can transform social conflict and create sustainable solutions for people and wildlife.[2] This could result in lasting outcomes related to prairie dog management on Thunder Basin National Grassland and enable an atmosphere of shared problem-solving that ultimately benefits both the people and wildlife.

II. Introduction

The U.S. Forest Service is proposing to amend prairie dog management direction in its 2001 Land and Resource Management Plan ("Management Plan") for the Thunder Basin National Grassland ("Thunder Basin" or "Grassland") to "place greater emphasis on control and active management of prairie dog colonies to address significant concerns related to health, safety, and economic impacts on neighboring landowners" as stated in the Scoping Cover Letter (p.1). The Forest Service has outlined its proposal in its Notice of Intent ("Scoping Notice") to prepare an Environmental Impact Statement ("EIS") (84 Fed. Reg. 16240), *2020 Thunder Basin National Grassland Plan Amendment, Scoping Document* ("Scoping Document"), and *Proposed Action: Changes to Grassland Plan Direction* ("Proposed Action"), made public on April 18, 2019.

We—Defenders of Wildlife ("Defenders"), Prairie Dog Coalition of the Humane Society of United States ("PDC"), and World Wildlife Fund ("WWF")—oppose the proposed amendment for Thunder Basin, as described by the Scoping Document and illustrated in the Proposed Action. It is likely to violate and fail to support the objectives of several federal laws, including the National Forest Management Act ("NFMA"), 16 U.S.C. §§ 1600 *et seq*.; the National Environmental Policy Act ("NEPA"), 42 U.S.C. §§ 4321 *et seq*.; the Endangered Species Act ("ESA"), 16 U.S.C. §§ 1531 *et seq*; and other laws. Not only is the proposed amendment likely to fail to comply with federal law, it will preclude recovery for the federally endangered black-footed ferret (*Mustela nigripes*; "ferret") and will put other imperiled species at an even greater risk of extinction. Importantly, it also ignores the root cause of the stated concerns by both livestock interests and conservation interests, which is lack of adequate implementation of the current plan's direction for both prairie dog management and conservation.

The proposal's substantial removal of protections to allow for more poisoning and shooting of prairie dogs does not change the issue of lack of past implementation, but it does lead to renewed and increased conflict on an issue that has been addressed previously and significantly in multiple public participation processes. This diversion of resources and time from current plan implementation to yet another plan amendment process will lead to more conflict, not less.

---

[2] Madden, F. and B. McQuinn. 2014. Conservation's blind spot: The case for conflict transformation in wildlife conservation. Biological Conservation. 178: 97-106.

We have financially and physically invested in restoring prairie dog populations for the important role they play in grassland conservation, including black-footed ferret recovery. On Buffalo Gap and Thunder Basin National Grasslands our three organizations have collaborated with the Forest Service and other stakeholders to secure, restore, protect, and expand ferret habitat. In addition, Defenders and WWF are longtime Executive Committee members of the U.S. Fish and Wildlife Service's Black-footed Ferret Recovery Implementation Team, the governing body for ferret recovery. Collectively, our organizations have invested millions of dollars to advance recovery of prairie dogs and ferrets on federal, tribal, and private lands in the North American Great Plains. We remain committed to conserving and restoring prairie dog populations on both grasslands because they are two of the few remaining, intact grassland habitats in North America capable of supporting viable black-footed ferret populations.

III. Failure to Implement the Current Management Plan, including the Black-tailed Prairie Dog Conservation Assessment and Strategy

If the Forest Service was adequately implementing the Grassland's Management Plan, including Amendment #3, and the Black-tailed Prairie Dog Conservation Assessment and Strategy ("Strategy") to reduce conflicts related to prairie dog conservation and management, this proposed amendment would not be needed. The Strategy was developed in 2009, and modified in 2015, to "provide overall guidance for prairie dog management on Thunder Basin National Grassland." Livestock grazing is one of the primary uses of the Grassland and surrounding state and private land. The Strategy includes a range of management tools to maintain viable populations of prairie dog and prairie dog associated species while also providing methods for inhibiting unwanted prairie dog colony expansion onto neighboring private lands.

Management options "are bounded by direction contained in the Revised Thunder Basin National Grassland Land and Resource Management Plan (2001 Grassland Plan) and the Record of Decision for the Thunder Basin National Grassland Prairie Dog Management Strategy and Land and Resource Management Plan Amendment #3 (2009)." Amendment #3 added a mandatory plan component to the Land and Resource Management Plan (Chapter 1 - Standard F-65b), which directed the Forest Service to "[a]dopt and implement a black-tailed prairie dog management strategy." Standard F-65b also made the Strategy "a part of" the Plan, giving it the force of law.

Developing Amendment #3 and guidance documents required considerable effort and resources from the Forest Service as well as multiple stakeholders who invested significant time in this process. The resulting strategies reflect compromises made by grazing lessees, nearby landowners, and wildlife conservation organizations. The components, objectives, and tools outlined in the Strategy provided the specific prescriptions for conserving prairie dogs to promote biodiversity and support persistence of prairie dog associated species—all vital for maintaining resistance, resilience, and redundancy in the prairie dog ecosystem of Thunder Basin's mixed-grass prairie, even in the face of plague. The Plan and Strategy ensure protections for wildlife, all the while enabling significant continued use of the Grassland for livestock grazing and allowing for actions to reduce livestock – prairie dog conflicts. Yet, after a promising start, the Forest Service has largely abandoned its commitments made in the Strategy.

The first year of the Strategy's implementation was in 2010. That same year, Defenders, the PDC, and WWF were invited by the Forest Service to lend our expertise to address expanding prairie dog populations within Management Area 3.63: Black-footed Ferret Reintroduction Habitat. Management Area 3.63 serves to provide "adequate amounts and distributions of occupied prairie dog colonies to support the reintroduction of the federally listed endangered black-footed ferret." The tools available in the Strategy to achieve this include prescribed fire, prairie dog translocation, buffer fences with tall vegetation, and sylvatic plague mitigation; the area also has a shooting restriction on prairie dogs. In addition to promoting prairie dog colony expansion in Management Area 3.63, the goal of implementing the Strategy is also to "proactively manage prairie dog populations on the TBNG in an environmentally, biologically, and socially acceptable manner" to prevent undesirable prairie dog colony expansion from the Grassland onto adjoining private lands.

In partnership with the Forest Service, with approval of the Wyoming Game and Fish Commission, and in accordance with the Management Plan and Strategy, we live-trapped prairie dogs from federal land colonies adjacent to private lands on the Management Area 3.63 perimeter and relocated them into the center of Management Area 3.63, applied deltamethrin dust to protect them from plague, and established two fenced buffers to discourage unwanted prairie dog colony expansion. As prairie dog populations began to expand, the Forest Service halted use of these tools, removed the shooting closure, and focused solely on lethal control of prairie dog colonies. Outlined below is the sequence of events that highlight how the Forest Service failed to adequately implement the Strategy, which led to the substantial expansion of prairie dog colonies in 2016/2017 in conflict areas near private lands followed by severe population declines in 2017/2018, including in areas where the plan calls for protections:

1. <u>The Forest Service discontinued the use of prescribed fire to expand prairie dog colonies in Management Area 3.63</u>. This occurred annually during 2009-2012 to promote prairie dog colony expansion and favorable habitat conditions for mountain plovers. It was halted by the Forest Service at the end of 2012 due to ". . .an unstable political climate surrounding prairie dog management Thunder Basin NG" (USFS, TBNG 2014: 3).
2. <u>The Forest Service discontinued the use of translocation</u> in 2012 (a non-lethal tool to mitigate conflicts and encroachment of prairie dogs on adjacent private lands) due to a request by the Wyoming Game and Fish Commission. "As with prescribed fire, due to an unstable political climate surrounding prairie dog management on Thunder Basin NG, translocation has been precluded as an implementation tool since 2011," (USFS, TBNG 2014: 4).
3. In 2012, in response to a complaint by an adjacent landowner, <u>the Forest Service removed one of the two permanent buffer fences</u> (constructed in 2010 to benefit the said landowner) along federal-private land boundaries designed to create a vegetative buffer and prevent future recolonization of the area by prairie dogs. The buffer that remained had been effective

according to Forest Service monitoring reports but the buffer that was removed due to landowner pressure returned to full prairie dog occupancy upon removal of the fence (USFS, TBNG 2014: 7).

4. The Forest Service rescinded the prairie dog shooting closure, beginning March 3, 2017, stating in the agency press release that it was due to "high populations of prairie dogs" and the need to "curb significant prairie dog colony expansion" (USFS, MBRNF & TBNG 2017). The closure was originally established in 2001 for Management Area 3.63. While the ban was apparently reinstated on March 27, 2019, closure signage has not been posted nor has an agency news release been circulated.
5. In 2017, the Forest Service halted the application of deltamethrin (to curtail plague) into prairie dog burrows within Management Area 3.63 even though active plague was occurring Grassland wide.[3]

Deputy Regional Forester Jacqueline Buchanan, during our June 14, 2017 meeting in Denver, acknowledged that the *Black-tailed Prairie Dog Conservation Assessment and Strategy* had not been properly executed.[4] The Forest Service did not adequately implement tools available and permissible in the Strategy to limit prairie dog colony expansion into unwanted areas. Per the examples above, the agency also did not adequately implement tools available to maintain colonies in Management Area 3.63 and other areas where desired. In fact, Forest Service leadership actively opposed implementation of conservation tools available. Offers from our organizations to provide materials and assistance to implement the conservation aspects of the plan in Management Area 3.63 were not accepted, and Regional Forester Brian Ferebee sent a letter to the Wyoming County Commissioners Association on May 19, 2017 assuring the commissioners that the Forest Service would not conduct plague mitigation measures on the Grassland. Soon after, a plague epizootic was first detected in June 2017 and quickly spread across the Grassland, reducing the active colonies on federal lands in and near Management Area 3.63 to approximately 600 acres (Scoping Document: 6).

These Forest Service decisions were not consistent with the Plan. Per the Strategy, "Plague management tools (e.g., dusting and vaccination) will be used where practical and effective to control plague within prairie dog complexes." Just after plague was detected on the Grassland, Defenders, PDC, and WWF made repeated requests in meetings and letters to the Forest Service to immediately apply deltamethrin dust to prairie dog burrows to protect prairie dogs in Management Area 3.63 that we collectively recovered. Application of deltamethrin, which our organizations had purchased and provided to Grassland managers, may have halted the spread of plague outbreak and promoted the conservation of

[3] Letter from Mr. Brian Ferebee, (Regional Forester of the Rocky Mountain Region) to the Wyoming County Commissioners Association. May 19, 2017; Email from Mr. Dennis Jaeger, Forest Supervisor (Medicine Bow-Routt National Forests, Thunder Basin National Grassland) to Wyoming County Commissioners Association, Subject: Short-term and long-term actions for Thunder Basin National Grassland. May 19, 2017.

[4] Letter from Chamois Andersen (Defenders of Wildlife), Lindsey Sterling-Krank (Prairie Dog Coalition), Kristy Bly (World Wildlife Fund) to Brian Ferebee (U.S. Forest Service, Denver Regional Office), Subject: Follow-up to meeting on Thunder Basin National Grassland. June 30, 2017.

mountain plovers and burrowing owls that had returned with the prairie dog recovery. This plague mitigation tool was denied on multiple occasions[5] by the Forest Service. The 2017/2018 plague event resulted in a near total loss of the prairie dog populations and associated wildlife species in Management Area 3.63 and beyond. In addition, the significant financial federal and non-federal conservation investments to recover prairie dog populations in this area were lost.

For nearly 12 years, our organizations have dedicated significant time, labor, and resources for prairie dog conservation within Management Area 3.63. Collectively, we have invested more than $200,000 toward a host of conservation efforts on Thunder Basin, including the translocation of prairie dogs from boundary areas of conflict near private land into the core conservation area when acreage was below the objective. Our organizations also purchased and donated deltamethrin, which was stored by the Forest Service and the National Black-footed Ferret Conservation Center and on hand if a plague epizootic occurred, but which has remained unused in recent years and, as noted above, prohibited from use by Regional Forester Ferebee's instruction.[6] This and other failures to manage Thunder Basin and Management Area 3.63 in accordance with the Plan and Strategy resulted in squandered resources, increased social conflict, and significant adverse impacts to the Grassland's wildlife and potential to serve as a critical part of ferret recovery.

IV. Status of black-footed ferret recovery

Approximately 350 black-footed ferrets live in the wild today, which is far short of the numbers needed to recover the species.[7] To remove the black-footed ferret from the Federal List of Threatened and Endangered Species, 3,000 breeding adult ferrets need to persist for three years at 30 sites (USFWS 2013). Of those 30 sites, 10 sites need to host at least 100 breeding adults and 20 sites need to host at least 30 breeding adults (USFWS 2013). Of the 29 reintroduction sites established to date, only half support active ferret populations, and most of these sites require continued supplementation of captive-bred animals.[8]

Notably, there are few sites in the ferret's range with sufficiently large prairie dog complexes to support 100 adult ferrets. In 2007, at the peak of ferret populations in the wild, there were only five reintroduction sites that hosted, or had the near potential to host, 100 breeding adults[9]. Today, there

are no reintroduction sites with 100 breeding adults due to sylvatic plague, drought, and other factors. Although efforts are underway to increase ferret numbers at those sites, at least five additional sites capable of hosting 100 breeding adult ferrets are needed to achieve delisting objectives.[10] With the right management approach, Thunder Basin has the potential to support 100 breeding adults; adoption of the Forest Service's proposed amendment, however, will preclude black-footed ferret recovery.

V. Need to Amend the Management Plan

A. NFMA and NEPA regulations require the Forest Service to adequately describe and justify a legitimate purpose and need to amend the Thunder Basin Plan.

Defining a "need to change" a national forest or grassland management plan under NFMA and its associated planning regulations ("2012 Planning Rule") (36 C.F.R. § 219) and a "purpose and need" for an action under NEPA and its associated regulations (40 C.F.R. § 1500) are closely related processes. After identifying a legitimate basis for changing a plan under the 2012 Planning Rule, the Responsible Official should then incorporate the need to change as an aspect of the purpose and need in NEPA documents associated with an amendment (FSH 1909.12, ch. 20, § 21.13(2); FSH 1909.12, ch. 20, § 21.21(4); FSH 1909.12, ch. 20, § 21.3(1)–(4)). This helps ensure consistency and compliance with both laws. Moreover, the requirement that there be a justifiable basis for amending a plan helps to ensure that the Forest Service wisely stewards the public's resources.

The Forest Service must provide justification for amending the Grassland Management Plan that meets the criteria established by NFMA. Although NFMA authorizes the Forest Service to amend forest plans, this authorization is accompanied by crucial limitations to prevent arbitrary amendments. Pursuant to the 2012 Planning Rule, an amendment must be based on a "preliminary identification of the need to change the plan," which may be based on "a new assessment; a monitoring report; or other documentation of *new* information, changed conditions, or changed circumstances" (36 C.F.R. § 219.13(b)(1) (emphasis added)). As the Forest Service recognizes, amendments are intended to keep plans "*current*, *effective*, and relevant" (FSH 1909.12, ch. 20, § 21.3). Forest Service Directives further caution that "[a] well-supported and effective rationale determining a need to change the plan *must be based on a good source of information*" (FSH 1909.12, ch. 20, § 21.2). In light of these limitations, an amendment that relies on irrelevant factors (such as outdated information or no-longer-extant conditions) would be arbitrary.

In sum, satisfying the letter and the spirit of NFMA and the Planning Rule requires the Responsible Official to present the new information and, importantly, to explain why the new information renders the existing forest plan language inadequate. This is not a political, but a science-based, inquiry. The Planning Rule states that "[t]he responsible official shall document how the best available scientific information ("BASI") was used to inform the amendment decision…" (36 C.F.R. § 219.3). Moreover,

---

[10] BFFRIT (Black-footed Ferret Recovery Implementation Team) Conservation Subcommittee, 2019. BFF [black-footed ferret] Site Estimates 2018, Table. Presented at April 10, 2019 meeting, Fort Collins, Colorado.

"[s]uch documentation must: Identify what information was determined to be the best available scientific information, explain the basis for that determination, and explain how the information was applied to the issues considered" (36 C.F.R. § 219.3). The planning Directives provide further support for and guidance to uphold these requirements (FSH 1909.12, ch. 20, § 21.2; FSH 1909.12, ch. 20, § 21.21).

With respect to NEPA regulations, a purpose and need statement should be brief but also specific (40 C.F.R. § 1502.13). However, the purpose and need for the amendment must be reasonable in light of the information the Forest Service has before it. The purpose and need cannot be defined as to make the Forest Service's preferred result "a foreordained formality." *Citizens Against Burlington, Inc. v. Busey*, 938 F.2d 190, 196 (D.C. Cir. 1991). Instead, "an agency should always consider the views of Congress, expressed, to the extent that the agency can determine them, in the agency's statutory authorization to act, as well as in other congressional directives." *Id*. Congress's views, of course, are reflected in statutes such as NFMA—and the ESA, which has made conservation and recovery of listed species an integral part of the Forest Service's mission. In light of the Forest Service's obligations under NFMA and NEPA to describe a legitimate, justified, and non-arbitrary basis for amending a plan, we discuss specifics of the Scoping Document below.

B. The Forest Service fails to demonstrate the need for a plan amendment.

1. The Scoping Document provided no direct evidence that "a new assessment; a monitoring report; or other documentation of new information, changed conditions, or changed circumstances" have emerged on the TBNG since Amendment #3 was implemented in 2009 (as required by 36 C.F.R. § 219.13(b)(1)).

The Scoping Document does not identify and document what new information provides the basis for changing the Management Plan in accordance with 36 C.F.R. § 219.13(b)(1). We recognize that the Draft Environmental Impact Statement (DEIS) will provide a more detailed analysis of conditions on Thunder Basin that purportedly justify changing the Management Plan. Yet the 2012 Planning Rule requires the "*preliminary identification* of the need to change be based on…*documentation* of new information, changed conditions, or changed circumstances" (36 C.F.R. § 219.13(b)(1)). Given the specificity presented in the need statements and Proposed Action, the Scoping Document should make stronger connections between the need statements and the supporting documentation required by the Planning Rule. Instead of specifically identifying and justifying a need for change, however, the Scoping Document makes non-specific inferences that only loosely connect with stated needs.

For example, the Scoping Document alludes to a "collaborative stakeholder group" convened by the State of Wyoming, which "provided a recommendation that has served as the basis for this proposed action" (Scoping Document: 5). To enable transparency, documentation of this collaborative process and rationale for the recommendation must be provided, and the Forest Service must include a list of non-governmental organizations (NGOs) that were included in this process and identify those that agreed to the recommendation. To be clear, this collaborative stakeholder group recommendation was *not* consensus-based and does *not* reflect the views or recommendations of the Conservation Organizations who have signed this letter.

As another example, the Scoping Document implies that the expansion of prairie dog colonies beginning in 2015 constitutes a significant change in Grassland conditions:

> Not long after the Forest Service completed an update to the management strategy in 2015, active prairie dog colonies on and around the Thunder Basin began to expand significantly. The population expansion continued into 2016 and 2017, exceeding anything seen in recent history (figure 2 and figure 3). Mapping efforts during these years showed that active prairie dog colonies expanded to over 75,000 acres, more than doubling the previous record for mapped acres. (Scoping Document: 5)

Prairie dog expansion in 2015-2017 does not constitute a significant change in Grassland conditions. The 75,000-acre number cited in the Scoping Document is for all landownerships in this general area, including private lands; 48,000 acres is the amount on federal land (Scoping Document: 6). The Biological Assessment and Evaluation for the 2001 Northern Great Plains Management Plans Revision (USFS 2001) accurately predicted and expected prairie dog colony expansion up to 48,000 acres on federal land even earlier, by 2011-12 “if drought conditions prevail and vegetation conditions are conducive” (p. 102).

Annual monitoring reports required by the Management Plan would be very useful in evaluating this issue, particularly because black-tailed prairie dogs are management indicator species. However, the Forest Service has not compiled any plan monitoring reports beyond 2011 (M. Nelson email May 13, 2019). Moreover, the Scoping Document is internally inconsistent with respect to prairie dog expansion justifying the need to change. The Scoping Document later notes that, “[i]n 2017, a plague event reduced the number of mapped acres by 99 percent to the current level of approximately 1,000 acres of active prairie dog colonies.” In other words, some information that the Forest Service is relying on was already out-of-date and invalid before the proposal to amend the plan was announced. One-thousand acres of prairie dogs – of which approximately 600 acres is on the Grassland in the vicinity of Management Area 3.63 – is well below any accepted scientific standard for enabling a viable ferret population and possibly for conserving well-distributed populations of prairie dogs and associated species across the grassland ecosystem.

In short, the Scoping Document fails to document new information, changed conditions, or changed circumstances that justify amending the Plan. Moreover, the information that is available (*e.g.*, the recent loss of significant active prairie dog acres to plague) does not support the proposed changes to the plan. Accordingly, the proposed amendment, as described by the Scoping Document and Proposed Action, is arbitrary.

2. The Forest Service’s stated purpose for the amendment is vague and arbitrary.

The Forest Service's stated purpose certainly adheres to the NEPA regulations' direction that it be "brief"—but it is otherwise deficient. The proposal to "to amend the grassland plan to better balance prairie dog colony conservation and control with other grassland uses" fails to "specify the underlying purpose" (40 C.F.R. § 1502.13) because it does not specifically define what "better balance" means. The Forest Service provides no explanation or evidence regarding how the grassland plan has resulted in a lack of "balance" among grassland uses. It provides no explanation or evidence how removing protections for a species that is a keystone for the grassland ecosystem (and critical for black-footed ferret recovery, in particular) is "better" for Thunder Basin. Without these explanations and this evidence, the proposed amendment appears to simply be political acquiescence. As discussed below, this perception is only bolstered by the stated list of needs, which appear to have been "reverse engineered" to fit the proposed action. Creating "needs" that point to a predetermined outcome can violate NEPA by, among other things, resulting in the improper elimination of the no-action alternative or alternatives that better support wildlife and listed species recovery.

3. The needs outlined in the Scoping Document, listed and addressed below, fail to demonstrate a necessity to amend the management plan.

The Scoping Document lists seven needs for the proposed amendment. None are accompanied by a science-based rationale or other adequate justification in the Scoping Document. We look at these in turn.

a) "Refocus management in management area 3.63, "black-footed ferret reintroduction habitat," to emphasize rangelands with short-stature vegetation that provide for multiple uses, including providing habitat for prairie dogs and associated species and providing livestock forage." (Scoping Document: 7)

This stated need is misleading. The proposal is not merely intended to ***refocus*** management area 3.63 management, but to ***eliminate*** the 3.63 management area designation from the Grassland entirely and stymie ferret recovery on the Grassland for the foreseeable future.

Simply "providing habitat" fails to meet requirements under 36 C.F.R. § 219.8 and 36 C.F.R. § 219.9 of the 2012 Planning Rule. Any amendment must ensure that the management plan maintains and restores the ecological integrity of the shortgrass prairie ecosystem, which many scientists call "the prairie dog ecosystem," because prairie dogs are essential to this system (Miller et al. 1994; Mulhern and Knowles 1996; Kotliar et al. 1999; Bangert and Slobodchikoff 2006; Hanson et al. 2007; Santos-Barrera et al. 2008). An amendment must take into account, for example, "[c]onditions in the broader landscape that may influence the sustainability of resources and ecosystems within the plan area" (36 C.F.R. § 219.8(a)(1)(iii)); thus, the amendment process and outcome must thoroughly address how livestock grazing affects grassland ecosystem conditions, including prairie dogs and associated species—not just how prairie dogs may be affecting livestock production (see Knopf 1996; Fuhlendorf et al. 2010; Kohl et al. 2013).

Further, the EIS for the amendment must take into account the level of prairie dog poisoning occurring in the "broader landscape," beyond the Grassland boundaries. The process and amendment must take into account "[s]ystem drivers, including dominant ecological processes, disturbance regimes, and stressors, such as natural succession, wildland fire, invasive species, and climate change," required by 36 C.F.R. § 219.8(a)(1)(iv); and the key driver of the shortgrass prairie ecosystem is the interactive disturbance regime of prairie dogs, bison, fire, and drought (Coppock and Detling 1986; Uresk et al. 1996; Truett et al. 2001), with periodic occurrences of extreme drought conditions like that which occurred in 2017 (Wang et al. 2019). Extensive poisoning removes prairie dogs from the equation and likely has significant effects that upset these natural processes.

b) "Delineate more logical boundaries for management area 3.63, for example by strategically using natural topographic and hydrologic barriers and incorporating boundary management zones." (Scoping Document: 7)

The Forest Service is proposing to have zero acres of management area 3.63 designated in the Grassland. Delineating management area boundaries based on natural barriers may make sense for reducing federal to private boundary conflicts, but the Forest Service must provide a rationale to support why this is a need. The purported need to change the boundaries of Management Area 3.63 is fundamentally undermined by the fact that the Forest Service intends to eliminate prairie dog protections within the area, as discussed next.

c) "Increase the availability of management options for prairie dog colony conservation and control, including lethal prairie dog control within management area 3.63." (Scoping Document: 7)

Discussion in the Scoping Document is limited to increasing the availability of management options for control; no examples of increased options for conservation are mentioned. Allowing an increase in lethal control in the 3.63 management area beyond the exceptions already allowed for private land and residence buffers undermines the management area designation's purpose: ferret recovery. Moreover, the Forest Service's Proposed Action indicates that the amendment will reduce the 3.63 area to zero acres and replace it with a new smaller 3.67 management area designation that will emphasize short stature vegetation but will deemphasize ferret recovery. Based on figures in the Proposed Action, roughly 8% (44,426 acres) of the Grassland is currently designated as management area 3.63, and prairie dog poisoning and shooting are largely allowed on the rest of the Grassland. At last count, as reported in the Scoping Document, the number of active prairie dog colonies on the Grassland in the vicinity of Management Area 3.63 had plummeted to approximately 600 acres; that's about 0.1% of the Grassland. Even at their presumed "record" level of 48,000 acres in the vicinity of Management Area 3.63 (Scoping Document: 6), prairie dog colonies accounted for less than 9% of the Grassland. This is right in line with the predicted range of variation in the 2001 LRMP (Biological Assessment and Evaluation, Appendix H: 102). The Forest Service must explain why it believes the current suite of management options is insufficient to conserve and control prairie dogs.

> d) "More effectively manage prairie dog colony encroachment from the Thunder Basin National Grassland onto private and state land. Encroachment concerns include public health, agricultural production, land values, facilities, and serving as a good neighbor as described in the record of decision for the grassland plan." (Scoping Document: 7)

The current management plan already provides the tools to address encroachment concerns. The Forest Service has not used them in recent years. (See Section III above for details and supporting information.) Increasing the areas where poisoning is allowable will not affect the encroachment issue.

> e) "Ensure management direction identifies habitat requirements needed to support viable populations of prairie dogs and associated species, such as mountain plover, burrowing owl, and swift fox, and that management would not preclude future reintroduction of black-footed ferret." (Scoping Document: 7)

The management plan must contribute to ferret recovery under the ESA and NFMA (see Sections VI and VIII below.) This must be included as a need for the plan amendment. Lowering the bar to "not preclude future reintroduction of black-footed ferret" is not adequate.

This statement also indicates there is a need to know the habitat requirements for supporting viable populations of these species. The Forest Service should conduct an amendment assessment (FSH 1909.12, Ch. 10, § 15) to ascertain whether current management direction does or does not support providing the habitat requirements for maintaining viable populations of the species listed in the need statement above and does or does not provide the ecological conditions to support a black-footed ferret population. The EIS must determine how the amendment changes projected future habitat conditions for these species.

Substantial analysis on the needs of associated species was completed as part of the 2001 LRMP EIS process and led to the current plan direction to manage for a minimum of 18,000 acres of prairie dog colonies in Management Area 3.63. The Proposed Action implies that this analysis was inaccurate and that far fewer, smaller, more scattered, and less protected acres of prairie dog colonies are adequate but provides no scientific basis for this stance.

> f) "Align with the Wyoming Game and Fish Department's "Wyoming Black-footed Ferret Management Plan" (2018)." (Scoping Document, p. 7)

The Forest Service is under no obligation to align any part of its management plan with Wyoming's Black-footed Ferret Management Plan or any state government wildlife management direction (36 C.F.R. § 219.4(b)(3)). Given that there is no statutory or regulatory basis for wholly subjecting federal management of federal public lands to the priorities of a state game agency, Wyoming's plan fails to provide a basis justifying the need to change Thunder Basin's existing management plan, including the 2009 Amendment #3 of Thunder Basin's land management plan. Despite the 2012 Planning Rule's instruction to coordinate with other government entities under 36 C.F.R. § 219.4(b)(1), the Forest Service cannot abdicate its statutory responsibilities to manage the federal public lands in line with Congress's direction.

Notwithstanding any state-federal cooperative agreements or memoranda of understanding, federal agencies have final responsibility for ensuring compliance with federal law. The ESA and NFMA require the Fish and Wildlife Service and the Forest Service to use their authorities to recover listed species and any purported veto power by the State of Wyoming (whether express or implied) is unlawful.

It is a common misconception that states represented by their wildlife agencies have ultimate management authority over wildlife. In fact, the courts have consistently upheld that the federal government has supremacy over its lands under the Property Clause of the United States Constitution (United States Constitution, Article IV, Section 3), which grants Congress the "Power to dispose of and make all needful Rules and Regulations respecting the Territory or other Property belonging to the United States." In *Kleppe v. New Mexico*, 426 U.S. 529, 541 (1976), the Court stated, "the 'complete power' that Congress has over public lands necessarily includes the power to regulate and protect the wildlife living there." *Kleppe* further described the limit of a state's ability to dictate policy on federal lands: "those powers exist only in so far as [their] exercise may be not incompatible with, or restrained by, the rights conveyed to the Federal government by the Constitution." *Id.* at 545 (internal quotes omitted). The Forest Service clearly has the authority to manage wildlife habitat and species populations (Schultz 2012). This includes managing the public's use of wildlife on national forests and grasslands.

Even if aligning with Wyoming's ferret plan was a legitimate action, the Forest Service's Proposed Action will move further away from making progress toward the Wyoming plan's objectives (WGFD and WBFFWG 2018: 11). Although the Forest Service states that ferret reintroduction would not be precluded, the prairie dog acreages and management actions in the proposal are insufficient to support 30 breeding adult ferrets, the minimum required to contribute toward recovery (USFWS 2013). Objective 1 calls for maintaining "a minimum of 341 breeding adults distributed among 5 or more populations statewide," and Wyoming currently contains only two ferret populations. Objective 2: "[m]aintain a minimum of 30 breeding adults in each population, with at least 2 populations containing a minimum of 100 breeding adults," is far from being achieved as only 1 site exists with this potential. Objective 3 aims to "[e]stablish at least 2 populations within white-tailed prairie dog colonies and at least 1 population within black-tailed prairie dog (*C. ludovicianus*) colonies," yet no ferret populations are known to occur on black-tailed prairie dog colonies in Wyoming and no potential black-tailed prairie dog recovery sites have been identified in the State.

Finally, the Forest Service fails to demonstrate how the current Thunder Basin Management Plan is out of alignment with the Wyoming Black-footed Ferret Management Plan. If the lack of alignment is a problem that is preventing the Forest Service from recovering ferrets on the Grassland, the agency must provide documentation that supports its preliminary identification of the need to change the plan. The current emphasis of ferret recovery in the 3.63 area aligns with the U.S. Fish and Wildlife's Black-footed Ferret Recovery Plan and even provides the opportunity for the Grassland to host a minimum of 100 breeding adults, which would greatly advance recovery of the species. If the Forest Service was actively working toward achieving the Wyoming plan's objectives, which would need to fall under federal authority and the ferret recovery plan, the agency would be better off fulfilling the requirements of its current plan so that ferrets could successfully be reintroduced at the 100-breeding adult level.

g) "Enhance engagement with partners for collaborative implementation of new plan direction." (Scoping Document, p. 7)

The meaning and implications of "collaborative implementation" must be clarified. A collaborative group should not be imposing management actions inconsistent with the Forest Service's statutory, regulatory, and plan obligations.

VI. Compliance with the National Forest Management Act

A. The Forest Service must meet NFMA's diversity requirement.

NFMA was enacted in 1976 in large part to elevate the value of ecosystems, habitat, and wildlife on our national forests to the same level as timber harvest and other uses. Specifically, NFMA requires the Forest Service to develop planning regulations that shall "provide for diversity of plant and animal communities based on the suitability and capability of the specific land area in order to meet overall multiple-use objectives" (16 U.S.C. § 1604(g)(3)(B)). In April 2012, the Forest Service finalized regulations implementing the NFMA (See 16 U.S.C. § 1604, 36 C.F.R. § 219). These regulations, the 2012 Planning Rule, established a process for developing and updating forest plans and set conservation requirements that the plans must meet to sustain and restore the diversity of ecosystems, plant and animal communities, and at-risk species.

Crucially, traditional Grassland uses under the multiple-use mandate do not trump NFMA's diversity requirement. Forest Service regulations call for "'integrated resource management,' directing the Forest Service to develop plans that provide for multiple uses '*while*' meeting the needs [of] sustainability and diversity. 36 C.F.R. § 219.10." *Fed. Forest Res. Coal. v. Vilsack*, 100 F.Supp.3d 21, 41 (D.D.C. 2015) (emphasis in original). "This means that the 2012 Planning Rule cannot be faulted for necessarily and inevitably requiring a reduction in [activities such as] timber harvest and grazing due to its sustainability mandates." *Id.* Closely related are NFMA's and the Planning Rule's substantive obligations on the agency to protect and recover species; these likewise cannot be ignored in pursuit of other expectations.

B. The Forest Service must comply with all applicable requirements of the 2012 Planning Rule.

1. Amending a plan (36 C.F.R. § 219.13)

a) The amendment process must be supported by a sufficient basis upon which to change the plan (36 C.F.R. § 219.13(b)(1)).

As demonstrated in Section V of these comments above, there is no information in the Scoping Document that provides a reasonable basis or justification for the Forest Service to expend its limited resources on gutting plan components that protect wildlife—and which are intended to help the agency comply with NFMA and other laws (such as the ESA).

b) The amendment process must provide opportunities for public participation (36 C.F.R. § 219.13(b)(2)).

We appreciate the Forest Service's efforts to engage us and willingness to communicate with us in the proposed amendment planning process. However, we are concerned about the transparency of the public process.

For example, despite our reasonable request, the Forest Service stated it would not make public the names and qualifications of the Interdisciplinary Team ("IDT") members at this time. It is the responsibility of the IDT to prepare plan amendments (36 C.F.R. § 219.5). Among other important guidance that the IDT be directly involved in the public participation process, the Planning Handbook states, "[t]he intensive public participation associated with collaboration is expected to support the following outcomes:"

> 3. Improved capacity of the Interdisciplinary Team and the public to reduce uncertainty by gathering, verifying, and integrating information from a variety of sources;
> …
> 5. Positive public perceptions of plans and the planning process; and
> 6. Increased trust and commitment to the final plan, with reduced potential for litigation.

(FSH 1909.12, ch. 40, § 43.1). Given the lack of transparency to this point, these outcomes appear uncertain for this proposed amendment.

Another example of the lack of transparency is the Forest Service's refusal to disclose the scientific information supporting the purported need to change the Plan before the release of the DEIS. Requirement 36 C.F.R. § 219.4 of the Planning Rule states,

> When developing opportunities for public participation, the responsible official shall take into account the discrete and diverse roles, jurisdictions, responsibilities, and skills of interested and affected parties; the accessibility of the process, opportunities, and information; and the cost, time, and available staffing. The responsible official should be proactive and use contemporary tools, such as the Internet, to engage the public, and should share information in an open way with interested parties.

The Conservation Organizations who have signed this letter offer a significant level of expertise and years of experience in this issue arena. In addition, there are many Black-footed Ferret Recovery Implementation Team Executive Committee members and other ferret, prairie dog, and prairie dog associated species researchers that could also provide relevant science and input to this process. The Forest Service's reticence in providing the information justifying its proposed action thwarts the ability of these many experts to do so—and further undermines the public's perception of and trust in the Forest Service's work.

c) The amendment process must comply with NEPA (36 C.F.R. § 219.13(b)(3)).

In Section VII below, we exhibit how, based on the content of its Scoping Document and Proposed Action, the Forest Service is failing to fully comply with NEPA.

d) New plan components must follow the applicable format for plan components as required by 36 C.F.R. § 219.7 of the planning rule (36 C.F.R. § 219.13(b)(4)).

As discussed in Section V above, the Forest Service has not justified the need for changing or adding plan components, and the undersigned Conservation Organizations disagree that new plan components are necessary. Should the Forest Service proceed, however, any plan direction added or modified by a plan amendment must stringently adhere to the Planning Rule. The Planning Rule provides a description and requirements of each type of plan component (36 C.F.R. § 219.7(e)(1)). The Planning Handbook provides additional guidance.

e) The Scoping Document referenced the substantive requirements directly related to the proposed amendment (36 C.F.R. § 219.13(b)(5)).

The Forest Service stated that the "[s]ubstantive requirements of the 2012 Planning Rule that are likely to be applicable to the amendment are in the Code of Federal Regulations (CFR) at 36 CFR § 219.8(a) "ecological sustainability" and (b) "social and economic sustainability;" 36 CFR § 219.9 "diversity of plant and animal communities;" and 36 CFR § 219.10(a) "integrated resource management for ecosystem services and multiple use" (Scoping Document: 1). While we agree these are the substantive requirements likely to be directly related to the proposed amendment, we reiterate that the proposed amendment process is unjustified and illegal.

f) The Forest Service must identify potential species of conservation concern (SCC) and plan for and manage these species "as if they were" SCC (36 C.F.R. § 219.13(b)(6)).

The Forest Service has indicated that it will identify potential species of conservation concern (SCC) during the proposed amendment development process. The proposed amendment substantially lessens protections for black-tailed prairie dogs, and will accordingly have substantial adverse impacts to the numerous associated species that rely on and benefit from prairie dogs—and possibly to other species, as well. The Planning Rule thus requires that "the responsible official must determine whether [any of those] species is a potential SCC, and if so, apply section § 219.9(b) with respect to that species as if it were an SCC" (36 C.F.R. § 219.13(b)(6)). Specifically, the Forest Service must:

1. Use the best available scientific information to determine whether the proposed amendment's effects will cause substantial concern about the species capability to persist over the long-term [in the plan area/on Thunder Basin/within Management Area 3.63] (36 C.F.R. § 219.9(c); § 219.13(b)(6));
2. Ensure that the modified/added plan components—including any necessary species-specific plan components—provide the ecological conditions necessary to main a viable population of each species (36 C.F.R. § 219.9(b)); and
3. Develop monitoring questions and indicators for ecological conditions required to maintain viable populations of each species (36 C.F.R. §§ 219.12(a)(5)(iii) & (iv); § 219.5(a)(3)).

If the Forest Service decides to continue developing the amendment after scoping, we urge the agency to develop and make public a draft potential SCC list early in the process—well before issuing its notice on the DEIS. The public should be given ample time to provide input on the species identified as SCC, the best available science used, and the process for making these selections. Indeed, the Forest Service's failure to release a list of the species it is considering identifying as potential species of conservation concern is *already* frustrating the public information and participation goals integral to both NFMA and NEPA. In a June 6, 2016, letter to regional foresters, (then) Deputy Chief Weldon stated that the *final* SCC decision should be made "well before the release of the draft environmental impact statement" "to allow the Forest Service to engage with the public about their concerns regarding the SCC before release of the DEIS."[11] The bottom line is this: the primary role of the NEPA process in relation to species of conservation concern is not to *identify potential SCCs but to address effects of the plan amendment on SCCs*, thus providing a basis for determining compliance with the NFMA viability requirement.

(1) Determinations of occurrence in the Plan Area

A species, which is not federally protected under the ESA, for which there is a substantial concern about persistence must be identified as a potential SCC if it is "known to occur in the plan area" (36 C.F.R. §

---

[11] Weldon, L.A.C. Deputy Chief, United States Forest Service. Clarification of implementation of the 2012 Planning Rule, Directives, and Regional Foresters Sensitive Species. June 6, 2016.

219.9(c)). In other management planning processes, the Forest Service has erred in rejecting species for SCC identification due to misinterpreting the identification criteria (FSH 1909.12, ch. 10, 12.52).

This is an example of a recurrent issue. According to the Planning Handbook, actual occurrence records may only be discounted if individual occurrences are “accidental” or “transient,” or are “well outside the species’ existing range” (which would presumably make them accidental or transient) (FSH 1909.12, ch. 10, 12.52(c)(1)). The Forest Service must identify migratory species as potential SCC when their seasonal range includes the Grassland. Seasonal habitat on forests for migratory species on forests or grasslands may be essential for maintaining species viability. This may also be true of habitat for some “transient” species in some areas and excluding such species in accordance with the Planning Handbook may violate the requirement of the Planning Rule to contribute to maintaining a viable population of the species within its range. Thus, the Forest Service must identify migratory bird species, such as the burrowing owl, as SCC.

(2) Determinations of substantial concern about long-term persistence

The Responsible Official must identify a species as a potential SCC if “the best available scientific information indicates substantial concern about the species' capability to persist over the long-term in the plan area” (36 C.F.R. § 219.9). “Concern” may be an inapt word choice in this case. The Planning Rule does not direct the Responsible Official to subjectively determine their own level of concern. The question to be addressed is whether the available scientific information indicates that a substantial risk to long-term persistence in the plan area exists. SCC and potential SCC determinations cannot be arbitrary; they must be informed by expert judgements about persistence. This is indicated by the various classifications specified in the Directives.

According to the Planning Handbook (FSH 1909.12, ch. 10, § 12.52b(3) and (4)), the Responsible Official must document the BASI used in identifying SCC. According to Planning Handbook (FSH 1909.12, ch. zero code, § 07.15), “citations should be one of the principal methods to show how the BASI was applied to the issues being considered.” The actual documents Responsible Official consulted to identify SCC must be referenced and available for public review. For each species considered and rejected, there should be at least one additional source of information referenced that indicates no substantial risk, and the regional forester must document “what information is most accurate, reliable and relevant” to the potential SCC determination in accordance with 36 C.F.R. §219.3. The process does not preclude staff professional judgment, but such judgment must be referenced and discussed in the same manner as other sources.

All Regional Forester Sensitive Species (RFSS) should be identified as potential SCC. The Forest Service classified RFSS as sensitive because their “population viability is a concern” (FSM 2670.5). In the Preamble to the Planning Rule, the Forest Service stated that SCC are similar to existing RFSS because population viability is a concern in each case (77 Fed. Reg. 21216).

The Responsible Official must consider the effect of broad-scale risk factors relevant to the plan area in the potential SCC identification process. The Planning Handbook (FSH 1909.12, ch. 10, § 12.52d(2)(a)) states that, “Species with NatureServe G/T1 or G/T2 status ranks are expected to be included (as SCC) unless it can be demonstrated and documented that known threats for these species, such as those threats listed for the species by NatureServe, are not currently present *or relevant* in the plan area.” In addition, § 12.52(f)(1) recognizes that SCC identification may be warranted by “stressors on *and off* the plan area.” When any source of SCC information suggests that a species is vulnerable in an area that includes the plan area, the Responsible Official must “determine what information is the most accurate, reliable, and relevant to” the persistence of the species in the plan area, in accordance with 36 CFR § 219.3 and use that to demonstrate that the factors outside of the plan area are not relevant to populations in the plan area, and that there is not substantial concern for their persistence in the plan area.

The Responsible Official should include for consideration species that have a NatureServe rank of S3 (state vulnerable). Though the Planning Handbook § 12.52d does not include the S3 ranking as a category that should be *considered*, a “vulnerable” ranking represents a scientific conclusion that there is a regional concern about long-term persistence.

2. Complying with relevant planning rule requirements

a) The plan amendment must “provide for social, economic, and ecological sustainability” as required by 36 C.F.R. § 219.8.

(1) Ecological sustainability and integrity

The Planning Rule requires that plan components “maintain or restore the ecological integrity of terrestrial and aquatic ecosystems and watersheds in the plan area” (36 CFR § 219.8(a)). The first step for assessments in the Planning Handbook is “Identifying the Ecosystems to Assess” for ecological integrity (FSH 1909.12, ch. 10, § 12.11). Compliance with the requirement for integrity of ecosystems cannot be determined without identifying the relevant ecosystems.

The Scoping Document lists a need for the amendment to refocus Management Area 3.63 management “to emphasize rangelands with short-stature vegetation” (Scoping Document: 7). The Proposed Action, summarized in the Scoping Document states, “[w]here possible, adopt use of the Natural Resources Conservation Service’s Ecological Site Descriptions in management area 3.67 as the basis to describe plant communities, evaluate current and desired conditions, and maintain or improve native vegetation and wildlife habitat.” (Scoping Document: 11). What is the definition and description of “rangelands with short-stature vegetation”? This is not clear from the from the list of ecological site descriptions on the Natural Resources Conservation Service’s webpage.[12] As we have recommended elsewhere, the Forest

---

[12] Natural Resource Conservation Service. Ecological Site Descriptions. https://www.nrcs.usda.gov/wps/portal/nrcs/main/national/technical/ecoscience/desc/.

Service should conduct an amendment assessment. Identifying and describing the ecosystems relevant to the proposed amendment is more appropriately addressed in an assessment *before* the EIS, a primary purpose of which is to disclose a proposed action's (and alternatives') impacts on known affected environment.

We believe it is essential that the Forest Service assess the role of prairie dogs, not only as a species that occurs in the Grassland's grassland ecosystem, but also as a keystone species and ecosystem engineer whose activities are a natural disturbance process for the ecosystem.

(2) Social and economic sustainability

Under the Planning Rule, management plans "must include plan components, including standards or guidelines, to guide the plan area's contribution to social and economic sustainability" (36 C.F.R. § 219.8(b)). In its Scoping Document for the amendment, the Forest Service stated, "[d]espite the ecological significance of prairie dogs, the animals cause widespread and significant concern related to public health, safety of humans and livestock, agricultural production, land values, and facilities" (Scoping Document: 2). The Forest Service must provide evidence, including quantitative data, demonstrating whether these concerns are founded.

Regarding public health concerns, for example, according to the Centers for Disease Control and Prevention (CDC), human plague cases averaged 7 per year between 2000 and 2017 across the United States, with 12 deaths during that time.[13] According to the Wyoming Department of Health, there have been 6 reported human plague cases in Wyoming since 1978.[14] Of course, any human death from a communicable disease is tragic. Yet, contracting plague is an extraordinarily low probability event. Plague, in humans, is treatable with antibiotics. Plague, in prairie dogs, can be prophylactically mitigated, and the current Plan, through the 2015 Management Strategy, specifically directs the Forest Service to do so. But the Forest Service refused to apply preventative measures when plague was first detected on the Grassland in 2017. We seriously question whether the existence of plague warrants the types and extent of management changes proposed by the Scoping Document and Proposed Action—but more importantly, the Forest Service's failures regarding plague mitigation obviate this issue as a valid reason to expend significant resources amending the plan, rather than correctly implementing existing direction.

b) The plan amendment must provide for the diversity of plant and animal communities as required by 36 C.F.R. § 219.9.

---

[13] Centers for Disease Control and Prevention, Plague. https://www.cdc.gov/plague/maps/index.html.

[14] Wyoming Department of Health, Infectious Disease Epidemiology Unit. https://health.wyo.gov/publichealth/infectious-disease-epidemiology-unit/disease/plague/.

(1) Ecosystem plan components to maintain or restore ecological integrity and ecosystem diversity (36 C.F.R. § 219.9(a))

The Planning Rule's requirement to develop plan components that maintain or restore ecological integrity requires the Forest Service to carefully consider the importance of parts of Thunder Basin for their value for wildlife and at-risk species. Specifically, Management Area 3.63 contains "ecological conditions, habitats, [and] key ecosystem characteristics…that are unique, under-represented, or rare across the broader landscape" (FSH 1909.12 ch. 20 § 23.11b)—namely the ability to achieve conditions necessary to support a wide-range of prairie dog associated species, including the reintroduction of a viable population of at least 100 breeding black-footed ferrets.

To develop the land management plan consistent with maintaining ecosystem diversity, the plan must include plan components, including standards or guidelines, designed to maintain, restore, or promote ecosystem diversity and habitat types. Moreover, when developing plan components for ecosystem diversity, the Forest Service should pay close attention to Thunder Basin's ability to contribute to the recovery of black-footed ferret and other at-risk species (FSH 1909.12 ch. 20, § 23.11d).

(2) The need for species-specific plan components (36 C.F.R. § 219.9(b))

Managing selected ecosystem characteristics for the diversity and integrity of ecosystems may not sustain populations of all native plant and animal species. The rule therefore requires species-specific plan components, if necessary, to provide the ecological conditions necessary to meet the various conservation requirements for individual at-risk species (36 C.F.R. § 219.9(b)). Together, ecosystem plan components and the species-specific plan components should provide ecological conditions to meet the NFMA requirement for diversity of plant and animal communities.

(a) The plan amendment must "contribute to the recovery of federally listed threatened and endangered species."

The Endangered Species Act requires federal agencies to, "utilize their authorities in furtherance of the purposes of [the ESA] by carrying out programs for the conservation[15] of endangered species and threatened species" (16 U.S.C. § 1536(a)(1)). (See Section VIII on ESA compliance.) NFMA, the Planning Rule, the planning process, and resulting management plans all shape the contours of the Forest Service's authorities that must be marshalled in the service of recovering listed species. Specifically, the 2012 Planning Rule establishes an affirmative regulatory obligation that forest plans "provide the ecological conditions necessary to: contribute to the recovery of federally listed threatened or endangered species" (36 C.F.R. § 219.9(b)(1)). As discussed in Section VI.A above, this planning

---

[15] "Conservation" is defined by the ESA to mean "the use of all methods and procedures which are necessary to bring any endangered species or threatened species to the point at which the measures provided pursuant to this Act are no longer necessary."

regulation supports NFMA's "diversity requirement." The development of forest plans that contribute to the recovery of listed species and reflect science-based conservation decisions is required to comply, not only with the ESA[16], but with NFMA as well.

(b) The plan amendment must maintain viable populations of SCC

As discussed above, an amended plan must protect potential species of conservation concern the same as designated species of conservation concern would be if they had been designated for the plan area. This means if there is any concern about whether the ecosystem plan components are inadequate to address a potential SCC's risk factors, then the responsible official must ensure the plan contains species-specific components (including standards or guidelines) to address those risk factors. See 36 C.F.R. § 219.9(b); FSH 1909.12 ch. 20, § 23.13. Importantly, a viable population is one "that continues to persist over the long term with sufficient distribution to be resilient and adaptable to stressors and likely future environments." 36 C.F.R. § 219.19. In evaluating this issue, the Forest Service must consider effects of actions outside the plan area in addition to those within the plan area.

c) The plan amendment must provide for ecosystem services and multiple uses as required by 36 C.F.R. § 219.10.

The Forest Service must describe and document the ecosystem services prairie dogs provide for the mixed-grass prairie ecosystem of the Grassland. Along with creating and maintaining habitat for a great diversity of species, prairie dog colonies and colony complexes provide a range of other ecosystems services.

VII. Compliance with the National Environmental Policy Act

The National Environmental Policy Act ("NEPA") has two objectives: (1) it requires an agency "to consider every significant aspect of the environmental impact of a proposed action"; and (2) "it ensures that the agency will inform the public that it has indeed considered environmental concerns in its decisionmaking process." *United States v. Coal. for Buzzards Bay*, 644 F.3d 26, 31 (1st Cir. 2011) (internal citations omitted). Stated another way, NEPA requires federal agencies to take a hard look at the environmental consequences of their actions before they act (See 42 U.S.C. §§ 4321, 4332(2)(C); 40 C.F.R. §§ 1501.2, 1502.25). The key element of this analysis is to evaluate the direct, indirect, and cumulative impacts—also referred to as effects—of several alternatives, including the proposed action, to determine whether an alternative with more conservation potential is available (See C.F.R. §§ 1502.16(a)-(b), 1502.25(c), 1508.16, 1508.27(b)(7)).

---

[16] The preamble to the planning rule specifically links this requirement to its responsibility under the ESA for recovery of listed species, stating, "[t]hese requirements will further the purposes of § 7(a)(1) of the ESA, by actively contributing to threatened and endangered species recovery and maintaining or restoring the ecosystems upon which they depend" (77 Fed. Reg. 21215).

The proposed amendment, detailed in the Proposed Action, delineates "major federal actions significantly affecting the quality of the human environment," and accordingly the Forest Service must prepare an EIS (42 U.S.C. § 4332(2)(C)). The Forest Service has committed to preparing an EIS, and we agree with this decision. Below we address additional duties of the Forest Service to ensure that it complies with NEPA.

A. The Forest Service must base its decisionmaking on the best available science.

The Scoping Document and Proposed Action reflect decisionmaking that is not based on sound science, which we have demonstrated in these comments (see Section VIII, for example). Federal agencies are required under NEPA to use "high quality" information in planning (40 C.F.R. § 1500.1(b)). The EIS is the primary vehicle for informing the planning process about the effects of plan components, and NEPA has its own requirements for scientific integrity of the discussions and analysis in environmental impact statements, including references to sources relied upon for conclusions in the EIS (40 CFR 1502.24). Also important, however, is that the Forest Service has incorporated the requirement to use best available scientific information into its NEPA obligations (FSH 1909.12, ch. zero code, § 7.11b).

Forest Service planning regulations require the use of best available scientific information to inform the planning process (see Section VI on NFMA). The December 2016 amendment to the Planning Rule added language to 36 CFR § 219.3 clarifying that the best available scientific information requirement applies to the plan amendment process (81 Fed. Reg. 90729). Compliance with the rule requires two tasks: the Responsible Official (1) "shall determine what information is the most accurate, reliable, and relevant to the issues being considered" (the definition of "best available"), and (2) document the "*basis* for that determination" (36 CFR § 219.3 (emphasis added)).

NEPA serves to protect the environment by ensuring "clarity and transparency" to federal decisions affecting the environment. *N.C. Wildlife Fed'n v. N.C. Dept. of Transp.*, 677 F.3d 596, 603 (4th Cir. 2012). Thus, it is critical that the information the Forest Service uses as a basis for its conclusions in the EIS be disclosed there. This is especially true for the effects on at-risk species. In particular, the Forest Service has a burden of proving assertions important to selection of alternatives.

Throughout these comments and appendices, we have presented much of the best available science that the Forest Service must strongly consider and incorporate into its analyses. Defenders and WWF are experts in black-footed ferret recovery and longtime Executive Committee members of governing body for ferret recovery, the USFWS's Black-footed Ferret Recovery and Implementation Team. PDC is an expert is restoring ferret habitat through prairie dog translocation. Again, as we request elsewhere and detail in Section IX, we strongly recommend the Forest Service conduct an amendment assessment. An assessment will be helpful for developing the effects analysis in the EIS, and most or all the information supporting that analysis should be provided in the assessment. The use of assessments, similar to transparency from the Forest Service, could increase trust in and the public's perception of the planning process.

B. The Forest Service must thoroughly consider alternatives and particularly the no-action alternative.

An evaluation of alternatives to the propose action is vital to an agency's informed decisionmaking and a core goal of NEPA (40 C.F.R. § 1502.1). Indeed, it is "the heart of the environmental impact statement" (40 C.F.R. § 1502.14). The EIS must "[r]igorously explore and objectively evaluate all reasonable alternatives" including "the alternative of no action" (40 C.F.R. § 1502.14(a)&(d)). Every alternative must be given "substantial treatment . . . in detail . . . so that reviewers may evaluate their comparative merits" (40 C.F.R. § 1502.14(b)).

As part of the requirement that the agency consider alternatives, NEPA and Council on Environmental Quality regulations mandate that the agency consider a no-action alternative in all environmental reviews (42 U.S.C. § 4332(2); 40 C.F.R. § 1502.14(d)). This alternative must be based on accurate and robust baseline data and describe the exceptional values of the Grassland for biodiversity and wildlife conservation, prairie dog and prairie dog associated species protection, potential as a ferret recovery site, and potential importance to national ferret recovery. Without a thorough and accurate description of the affected environment, there is simply no way to determine what effect the proposed amendment will have, and, consequently, no way to comply with NEPA (40 C.F.R. § 1502.15). Moreover, to meet Forest Service's NEPA obligations, consideration of the no-action alternative must be vigorous and far-reaching. Such consideration would involve closely analyzing impacts—including beneficial impacts—on prairie dogs, associated species, and the prospects for black-footed ferret recovery.

As we discussed above, the current management plan for the Grassland has not been fully or properly implemented. And we urge the Forest Service to select the no-action alternative as its preferred alternative for the DEIS. To be fully clear, we do not support the proposed action alternative—or any alternative that would further weaken protections for prairie dogs and associated species, or the potential to establish a ferret population as outlined in the current Management Plan.

C. The Forest Service must analyze and fully disclose in the EIS the adverse impacts of the proposed amendment to the grassland ecosystem and numerous wildlife species.

An EIS must take a hard look at the direct, indirect, and cumulative effects of the proposed amendment on the human environment as well as means to mitigate adverse environmental impacts, including ecological impacts (40 C.F.R. §§ 1502.16, 1508.25(c)). The EIS for the proposed amendment must evaluate the effects in a way that will meaningfully inform decisionmakers and the public about likely outcomes. Stated another way, the effects analysis needs to be more than a subjective, qualitative, and comparative analysis—it requires in-depth analyses of significant issues (40 CFR §1501.7(a)(2)), such as species viability requirements. Below is a non-exhaustive list of topics and issues that should be thoroughly analyzed and considered in the EIS:

- The analysis must detail how specific proposed plan components affect each ecological condition needed by at-risk species. It is fundamental that the EIS properly characterize what the plan components direct the Grassland to do.
- The EIS analysis must properly account for the effects of removing protective standards from the current plan. Some plans seem to have a core assumption that more flexibility is good, and therefore that standards should be limited. Standards provide greater certainty that activities having adverse effects will not occur, though we do not support the proposed standard modifications, removals, and additions in the Proposed Action.
- The Forest Service must also address broad-scale effects during management planning. Cumulative effects can include all factors "beyond the authority of the Forest Service" (36 CFR § 219.9(b)(2)) including activities of state and local entities that impact wildlife and biodiversity in the region.
- The EIS must also disclose and address uncertainty and risk. NEPA requires disclosure of incomplete or unavailable information (40 CFR § 1502.22). For at-risk species, it is especially important to characterize the level of uncertainty and the effects in terms of how plan components increase or decrease risk.

D. The Forest Service must conduct a Biological Evaluation for each threatened or endangered species, Regional Forester Sensitive Species, and potential Species of Conservation Concern likely to be affected by the amendment.

The Forest Service should follow national-level direction (FSM 2600, ch. 2670, 2005) and Regional 2 direction (FSM 2600, ch. 2670, 2018) for developing biological evaluations. Species that must be evaluated in the biological evaluation include the following, at minimum: black-footed ferret; black-tailed prairie dog, species associated with prairie dogs—mountain plover, burrowing owl, swift fox, ferruginous hawk, and others; all Regional Forester Sensitive Species, all potential Species of Conservation Concern.

Additionally, to meet the Planning Rule requirements, as guided by FSH 1909.12, ch. 10, § 12.14a, the Forest Service must describe the natural range of variation of prairie dog disturbance across the landscape. The DEIS must determine the effects of setting the limits on prairie dog colony acreage and distribution described by the Scoping Document and Proposed Action. This information must be included in the biological evaluation.

VIII. Compliance with other applicable laws

A. The amendment must comply with the Endangered Species Act.

The black-footed ferret was one of the first species in the United States designated as endangered by U.S. law. It was first listed under the Endangered Species Preservation Act of 1966 (32 Fed. Reg. 4001, 4001 (Mar. 11, 1967) and has remained listed ever since. The species is currently designated endangered under the Endangered Species Act of 1973. 50 C.F.R. § 17.11(h) (current list of endangered and threatened wildlife).

Five black-footed ferret sightings were documented on Thunder Basin between 1971 and 1977 (USFS, MBNF & TBNG 1985). The last ferret was observed on the Grassland in 1981 (USFS, MBNF & TBNG 1985).

Though black-footed ferrets do not currently occupy Thunder Basin National Grassland, the Forest Service is nonetheless obligated under the ESA to promote their recovery. Congress enacted the ESA to provide "a program for the conservation of . . . endangered species and threatened species" (16 U.S.C. § 1531(b)). Section 2(c) of the ESA establishes that it is "the policy of Congress that all Federal departments and agencies shall seek to conserve endangered species and threatened species and shall utilize their authorities in furtherance of the purposes of this Act" (16 U.S.C. § 1531(c)(1)). Section 7(a)(1) of the Act mandates that federal agencies "utilize their authorities in furtherance of the purposes of this Act by carrying out programs for the conservation of endangered species and threatened species" (16 U.S.C. § 1536(a)(1)). The ESA defines "conservation" to mean "the use of all methods and procedures which are necessary to bring any endangered species or threatened species to the point at which the measures provided pursuant to this [Act] are no longer necessary" (16 U.S.C. § 1532(3)).

The current (Donald R. (Pete) Gober) and former (J. Michael Lockhart) USFWS Black-footed Ferret Recovery Program coordinators have long noted the importance of federal land management agencies complying with Section 7(a)(1) of the ESA to promote ferret recovery, stating in 2006,

> Federal public lands (national grasslands, Bureau of Land Management property, national wildlife refuges, national parks and monuments, and military lands) should bear a disproportionate amount of habitat development. Responsibilities under section 7(a)(1) of the ESA (a provision requiring all Federal agencies to fully promote and support endangered species recovery) should be reinforced at the national level, both with funding and refocused priority, to establish and manage large prairie dog complexes wherever possible. (Lockhart et al. 2006: 18)

The USFWS recently affirmed the importance of Thunder Basin for this recovery effort:

> TBNG is one of the few large grassland properties with extensive black-tailed prairie dog populations and accordingly is of particular interest as a site that has extremely high potential to contribute to the recovery of the endangered black-footed ferret (ferret). In fact, TBNG may well be the best existing potential site across the species' range in 12 western states, Mexico, and Canada that could significantly contribute to ferret recovery at the present time. [17]

---

[17] United States Department of Interior, U.S. Fish and Wildlife Service. 2017. Letter to Mr. Brian Ferebee (Regional Forester, U.S. Forest Service, Rocky Mountain Region) from Ms. Noreen E. Walsh (Regional Director, U.S. Fish and Wildlife Service, Mountain-Prairie Region). May 30.

The USFWS's black-footed ferret recovery delisting objectives (USFWS 2013: 6, 62) are to:

- Establish ≥3,000 free-ranging breeding adult black-footed ferrets in 30 or more populations, with at least one population in each of at least 9 of 12 States within the historical range of the species, with no fewer than 30 breeding adults in any population, and at least 10 populations with 100 or more breeding adults.

- Maintain these population objectives for at least three years prior to delisting.

Notably, there are few sites in the ferret's range with sufficiently large prairie dog complexes to support 100 adult ferrets. In 2007, at the peak of ferret populations in the wild, there were only five reintroduction sites that hosted, or had the near potential to host, 100 breeding adults.[18] Today, there are no reintroduction sites with 100 breeding adults due to sylvatic plague and drought conditions. Although efforts are underway to increase ferret numbers at the five sites that were nearing 100 breeding adults in 2007, five additional sites capable of hosting 100 breeding adult ferrets are needed to achieve delisting objectives.[19] Ensuring that Thunder Basin National Grassland is one of those five sites is essential to ferret recovery. Adoption and implementation of this proposed amendment will preclude recovery of the species.

Thunder Basin has been considered a promising black-footed ferret recovery site for decades. However, the proposed amendment indicates the Forest Service is abandoning its long-standing efforts to honor its Section 7(a)(1) obligation. Since at least 1985—and until the current proposed amendment—the Forest Service has developed and implemented management prescriptions, administered projects, and undertaken other actions to provide the conditions necessary for black-footed ferret recovery and reintroduction on Thunder Basin.

The Forest Service has consistently and specifically protected prairie dog colonies to provide habitat for ferret reintroduction. As scientific understanding of the prerequisites to successful black-footed ferret reintroduction has been refined, the Forest Service's actions on Thunder Basin related to ferrets centered around implementing greater protections of prairie dogs over larger portions of the Grassland to expand prairie dog colonies to facilitate ferret recovery. This is evident from the Forest Service's Biological Assessment (BA) for the 1985 management plan, which recognizes the need to protect potential, though currently unoccupied, black-footed ferret habitat:

> Prairie dog towns are considered the primary black-footed ferret habitat providing a year around food source and shelter (Hillman 1968, Henderson et al. 1969, Linder et.al. 1972). Prairie dog town mapping activities on the Grassland during 1979 through 1984 have indicated

---

[18] BFFRIT (Black-footed Ferret Recovery Implementation Team) Conservation Subcommittee, 2019. BFF [black-footed ferret] Site Estimates 2018, Table. Presented at April 10, 2019 meeting, Fort Collins, Colorado.

[19] BFFRIT (Black-footed Ferret Recovery Implementation Team) Conservation Subcommittee, 2019. BFF [black-footed ferret] Site Estimates 2018, Table. Presented at April 10, 2019 meeting, Fort Collins, Colorado.

> approximately 100 prairie dog towns totaling 13,046 acres to be located on Forest Service administered lands. All these prairie dog towns can be considered potential black-footed ferret habitat. (USFS, MBNF & TBNG 1985: G-7)

In turn, the 1985 management plan specifically identified land areas of the Grassland to focus on prairie dogs and ferret reintroduction. The Final Environmental Impact Statement for the Medicine Bow National Forest and Thunder Basin National Grassland Land and Resource Management Plan of 1985 plan stated, "[a]pproximately 2,240 acres of prairie dog towns have been identified as potential habitat for the black-footed ferret. These areas are managed for black-footed ferret habitat …" (USFS, MBNF & TBNG 1985: III-46). The 1985 management plan also designated the black-footed ferret a "recovery species."

Notably, the 1985 plan was finalized before the 1988 Black-footed Ferret Recovery Plan recovery criteria were developed. Yet the USFWS's Biological Opinion (BO) for the 1985 plan demonstrates that the Service fully expected that the Forest Service would continue managing and protecting prairie dogs, despite the absence of ferret occupancy, to prepare for future reintroduction:

> Our concurrence of "no affect" [*sic*] on the black-footed ferret is based on established and continuing Forest Service commitments to the Thunder Basin Prarie [*sic*] Dog Management Plan which provides guidance on conducting surveys for ferrets on prairie dog towns for management actions or other disturbance proposals. In addition, the Forest Service is commited [*sic*] to maintaining a potential 5400 acres of prairie dog towns with about 2240 of these towns identified as "potential" ferret habitat. … We encourage research on the dynamics of the prairie dogs on the Grassland in order to help develop management plans for prairie dog town complexes used for ferret reintroduction projects in the future. (USFS, MBNF & TBNG 1985: G-2)

Subsequent annual monitoring reports for the 1985 management plan indicate the Forest Service was tracking potential ferret habitat on the Grassland. For example, the 1998 monitoring report, stated, "[h]abitat capability is summarized as increasing for: bald eagle, black-footed ferret, black-tailed prairie dog, and Mountain plover" (MBNF 1998: unpaginated).

By 2001, the scientific understanding of what constitutes high quality ferret habitat and what minimum prairie dog complex sizes are needed to support viable ferret populations evolved. In a letter from (then) USFWS ferret recovery coordinator, Mike Lockhart to Bob Luce (black-tailed prairie dog interstate coordinator), dated March 16, 2001, Mr. Lockhart states:

> … the only true measure of ferret reintroduction success to date suggests that high density, plague-free, black-tailed prairie dog complexes in excess of 10,000 acres, with large core colonies, and which are not subject to artificial perturbations (e.g., shooting/poisoning) are needed to reestablish wild ferret populations. Conversely, ferret reintroductions into smaller,

> more isolated, prairie dog complexes, have not successfully established stable ferret populations, even in complexes with relatively high prairie dog densities.[20]

In line with Mr. Lockhart's expert recommendations, Thunder Basin National Grassland's 2001 Land and Resource Management Plan designated the 3.63 Management Area for "Black-footed Ferret Reintroduction Habitat," and prioritized that, "[b]lack-tailed prairie dog colony complexes are actively and intensively managed as reintroduction habitat for black-footed ferrets" (USFS, TBNG 2001: 3-16).

Consistent with the Forest Service's Section 7(a)(1) obligations, the 2001 LRMP also prescribed the desired condition that "[l]arge prairie dog colony complexes are established and maintained as suitable habitat for black-footed ferret reintroductions. Land uses and resource management activities are conducted in a manner that is compatible with maintaining suitable ferret habitat" (USFS, TBNG 2001: 3-16). Furthermore, the Forest Service did not consider landowner resistance a prompt to abandon the aim of the Grassland to serve as a ferret recovery site, but rather to find workable alternatives:

> The Forest Service works with other agencies and organizations to pursue conservation agreements or easements with adjoining land jurisdictions to achieve black-footed ferret recovery objectives. Where landownership patterns are not conducive to effective and successful prairie dog and black-footed ferret management, landownership adjustments with willing landowners may also be used to help resolve management issues. (USFS, TBNG 2001: 3-16)

The 2001 LRMP also included strict standards to protect the 3.63 Management Area such as conditions on the use of rodenticides and direction to prohibit shooting within ferret reintroduction habitat. (USFS, TBNG 2001: 3-17).

In 2001, the Forest Service banned shooting on 72,500 acres of prairie dog habitat on Thunder Basin (Matthews et al. 2001).[21] Buseck et al. (2005: 25) stated, "[t]his ban is one of the first of its kind on public lands." The shooting restrictions were intended "to allow populations to expand in anticipation of black-footed ferret reintroduction" (Buseck et al. 2005: 35).

More recently, Luce (2006), at the time recently retired from the Wyoming Game and Fish Department, listed Thunder Basin as one of three "immediate potential sites" for black-footed ferret recovery. Luce (2008) conducted an inventory of potential ferret recovery sites across the species historic range and again included Thunder Basin in his list of potential sites. Luce (2008: 36) noted the positive potential for intra-jurisdictional land units to coordinate ferret recovery, stating,

---

[20] Letter from Mr. J. Michael Lockhart (USFWS, Black-footed Ferret Recovery Coordinator) to Mr. Bob Luce (Black-tailed Prairie Dog Interstate Coordinator. March 16, 2001.

[21] In 2010, the Forest Service expanded the shooting area closure from 72,500 acres to 100,460 (USFS, TBNG 2014).

> Entities within the same jurisdiction such as Wind Cave, Badlands, and Theodore Roosevelt National Parks should consider the individual parks as components of a mega-reintroduction site. National Grasslands, including Thunder Basin, Little Missouri, Cimarron, Kiowa, Comanche, Pawnee, and others could function similarly within the U.S. Forest Service. This approach would facilitate interchange of management approaches and translocation of black-footed ferrets between sites.

Prior to a plague outbreak in 2001, about 18,000 acres of occupied prairie dog colonies occurred on the Grassland, and close to 20,000 acres in the region with the inclusion of state lands in the count (Luce 2008).

After a long-term stakeholder effort, the Forest Service implemented Amendment #3 to the 2001 LRMP. Though the Forest Service modified Management Area 3.63 and prairie dog management tools to enhance community support, Amendment #3 to the 2001 LRMP reiterated that Thunder Basin would serve as a ferret reintroduction site, and the Forest Service would protect and manage a sufficient area of active prairie dog colonies to meet the USFWS's recovery plan objectives. As stated in the Record of Decision for Amendment #3 of the Management Plan,

- The Category 1 Prairie Dog Habitat has a management objective of at least 18,000 acres of active prairie dog colonies. The acreage in Category 1 is not capped at 18,000 acres but would be allowed to grow within the boundary of the Management Area 3.63. (USFS, TBNG 2009: 3)

- Any prairie dog control efforts to address unwanted colonization onto non-federal lands within Category 1 Prairie Dog Habitat proposing to use rodenticides may only be initiated if cumulative acreage of active prairie dog colonies within Category 1 exceeds 18,000 acres. (USFS, TBNG 2009: 4)

- Category 1 Prairie Dog Habitat will be considered core habitat. Recreational shooting of prairie dogs will be prohibited year-round within Category 1 Prairie Dog Habitat. (USFS, TBNG 2009: 3)

In short, facilitating the reintroduction (and recovery) of black-footed ferrets has long been a Forest Service goal on Thunder Basin—one that is integral to ensuring that the Forest Service is complying with its Section 7(a)(1) obligations.

By 2017, in response to complaints by a few landowners and lessees to state and federal officials in Wyoming regarding prairie dog management on the Grassland, the Forest Service began signaling its change in direction and abdication from managing the Grassland in a way that complies with Section 7(a)(1) of the ESA. Communications make clear the Forest Service is acquiescing to political pressure to weaken prairie dog conservation measures intended to provide ferret suitable habitat. On May 19, 2017, Regional Forester Ferebee of the Rocky Mountain Region of the Forest Service sent a letter to the Wyoming County Commissioners Association, with a copy to Governor Mead, outlining a list of actions the Forest Service would take that would detrimentally impact progress toward ferret recovery: prohibit plague mitigation, increase prairie dog poisoning, and explore the use Rozol[22] (Ferebee, USFS 2017). In response, we (Defenders of Wildlife, Prairie Dog Coalition of the Humane Society of the United States, and World Wildlife Fund) communicated our concerns in a series of letters and in-person meetings to the Forest Service (and others). Except for anticoagulant use to which the Forest Service will not permit, these concerns have not been alleviated.

More recent statements and letters also illustrate the agency's recent aversion to complying with ESA mandates. A December 4, 2017 Interagency Statement (USFS, MBRNF & TBNG et al. 2017) between Forest Service, USFWS, and Wyoming Game and Fish Department declared,

> We cooperatively agree that the reintroduction of black-footed ferrets on the Grassland is not appropriate at this time. Instead, the current focus surrounds prairie dog management actions, including boundary control and disease control. The U.S. Forest Service will monitor ecological progress and grassland restoration activities on the Grassland. Interaction with stakeholders will continue on these important issues.[23]

With no clear grounding in science, law, or policy, political pressure from Wyoming government leaders seems to have influenced the Forest Service. On December 3, 2018, the Select Federal Natural Resource Management Committee of the Wyoming Legislature (2018), represented by co-chairs Senator Michael Von Flatern and Representative Tyler Lindholm, sent a letter to the WYGD, Forest Service (Rocky Mountain Region), and USFWS (Mountain-Prairie Region),

> We strongly urge your agencies to not include the Grassland as a potential reintroduction site for black-footed ferrets in any future memorandum of understanding or interagency agreement. There are several issues that must be resolved before reintroduction, including boundary control, dedicated funding for boundary and plague control, and the lack of support from landowners adjacent to the Grassland and in surrounding areas. We also believe that it would be prudent to delay considering the Grassland as a reintroduction site until the Thunder Basin National Grassland Land and Resource Management Plan is amended to allow for better management of the prairie-dog population. In materials provided to the Committee in September, the Wyoming Game and Fish Department, the Wyoming Department of Agriculture, the United States Forest Service, and the United States Fish and Wildlife Service stated that they do not support ferret reintroduction on the Grassland until these issues are resolved.

---

[22] Rozol is an anticoagulant toxicant believed to be more effective at killing prairie dogs than other rodenticides, like zinc phosphide, but it also comes with a greater risk of killing non-target predators that eat poisoned prairie dogs. (*See* Letter from Regional Director Noreen Walsh, USFWS, to Regional Forester Brian Ferebee, USFS (May 30, 2017)). At Footnote #1.

[23] The existing management plan contains robust provisions to ensure adequate boundary and disease control to address local concerns, but the Forest Service has repeatedly failed to use them. (See Section III above).

Despite the Wyoming Select Committee's letter that suggests resolving landowner conflicts, the Scoping Document for the amendment and the Proposed Action propose stripping current plan direction to work with landowners to progress toward ferret recovery.

That the Forest Service is acting on politics and landowner interests rather than science or law is evident throughout the Scoping Document. The Forest Service is proposing to replace the designated ferret reintroduction habitat on Thunder Basin with a focus on "rangelands with short-statured vegetation" that allows prairie dog area reductions, by lethal and other means, when the total active prairie dog acres exceeds 7,500, with exceptions to also allow for reductions when below 7,500 as well as blanket approval for "density control" (or scattered poisoning throughout) at any time (Scoping Document: 11). The agency further proposes that active prairie dog colonies "be distributed across the landscape and vary in size, up to approximately 1,000 acres, with an emphasis on colonies of 100 to 400 acres," with at least one colony complex to "be managed for at least 1,500 acres of active prairie dog colonies" (Scoping Document: 11).

The goal of managing for the very minimum size of active colonies to allegedly support associated species meets no credible best available science threshold for supporting a viable black-footed ferret population—especially where these colonies are fragmented across the management area and face persistent shooting and poisoning. Moreover, the Forest Service has not provided a scientific basis supporting its proposed emphasis on 100- to 400-acre colonies. Although the USFWS suggests 1,500 acres as a minimum for consideration to begin a ferret reintroduction effort into black-tailed prairie dog colonies in its Safe Harbor Agreement, that number is well below the size of colonies supported by science in the recovery plan as well as empirical evidence at Conata Basin necessary to sustain a population (USFWS 2013). Moreover, there is no 1,500-acre recovery site in North America today that hosts or is even capable of hosting the required 30 breeding adults to count towards downlisting or delisting the species.[24]

The Scoping Document (p. 7) includes the following need statement in the Purpose and Need section:

> Ensure management direction identifies habitat requirements needed to support viable populations of prairie dogs and associated species, such as mountain plover, burrowing owl, and swift fox, and that management would ***not preclude future reintroduction of black-footed ferret***. (emphasis added)

"Not preclude" is significantly different than "conserving," as defined in the ESA, or "recovering," and does not meet the spirit and mandate of Section 7(a)(1) of the ESA. The Forest Service proposed amendment will not meet the minimum requirements for managing adequate ferret recovery habitat or establishing a ferret population that will contribute to federal recovery objectives or persist into the foreseeable future.

---

[24] BFFRIT (Black-footed Ferret Recovery Implementation Team) Conservation Subcommittee, 2019. BFF [black-footed ferret] Site Estimates 2018, Table. Presented at April 10, 2019 meeting, Fort Collins, Colorado.

Moreover, the proposed amendment likely does not even meet the Forest Service's baseless "not preclude" standard. If the proposed amendment will support viable populations of prairie dogs at all, those populations will be small, fragmented, and likely routinely subject to poisoning, shooting and harassment, and potential extermination due to plague. Without robust and resilient prairie dog populations, there will be no opportunity to successfully recover ferrets to Thunder Basin. The loss of Thunder Basin as a reintroduction site must be further viewed through the lens of black-footed ferret recovery as a whole. Delisting the ferret will require at least 10 populations with 100 or more breeding adults, and—as the USFWS acknowledges—Thunder Basin is one of only a few sites on federal lands with the potential to support that size population.[25]

Thunder Basin's 1985 and 2001 management plans, including Amendment #3, and the 2015 Black-tailed Prairie Dog Conservation Assessment and Management Strategy for the Thunder Basin National Grassland all maintain the expectation that ferrets would be reintroduced to the Grassland. The Forest Service has dedicated close to 35 years preparing the Grassland for ferret recovery by managing prairie dogs at numbers that would allow for the species to return to the Grassland. By abandoning the 3.63 Management Area designation and plan standards meant to protect prairie dog habitat specifically for ferret recovery, the proposed amendment would break not only precedent, but the law.

B. The amendment must comply with the Migratory Bird Treaty Act.

The Forest Service must comply with the Migratory Bird Treaty Act (MBTA) in the development of the amendment (16 U.S.C. §§ 703-712). The Grassland is part of the breeding range for least 16 migratory birds protected by the MBTA (IPaC, accessed May 11, 2019) (see table below). The MBTA makes it unlawful "at any time, by any means or in any manner, to pursue, hunt, take, capture, kill, attempt to take, capture, or kill, [or] possess . . . any migratory bird" unless otherwise permitted by regulation (16 U.S.C. § 703). Any take or kill of migratory birds on the Grassland without authorization would violate the MBTA.[26] The Forest Service must address how it will ensure compliance with the MBTA in relation to the proposed amendment in the DEIS.

Migratory Bird Species	Breeding Season	USFWS Bird of Conservation Concern
Bald Eagle	Dec 1 to Aug 31	

---

[25] United States Department of Interior, U.S. Fish and Wildlife Service. 2017. Letter to Mr. Brian Ferebee (Regional Forester, U.S. Forest Service, Rocky Mountain Region) from Ms. Noreen E. Walsh (Regional Director, U.S. Fish and Wildlife Service, Mountain-Prairie Region). May 30.

[26] The validity of the Department of Interior's recent attempt to reverse its longstanding interpretation of the MBTA (as reflected in Solicitor Opinion M-37050) is currently under review. *See Nat'l Audubon Society v. U.S. Dept. of the Interior*, 18-cv-04601 (S.D.N.Y. filed May 24, 2018). The reversal is at odds with multiple court rulings regarding the application and enforcement of the MBTA. *See, e.g., U.S. v. FMC Corp*, 428 F.Supp. 615 (W.D.N.Y. 1977), *aff'd*, 572 F.2d 902 (2nd Cir. 1978); *see also* Solicitor Opinion M-37041, "Incidental Take Prohibited Under the Migratory Bird Treaty Act" (Jan. 10, 2017).

C. The amendment must comply with the Bald and Golden Eagle Protection Act.

Both bald eagles and golden eagles occur and nest in the Grassland (Gaines 1996). Both species are protected under the Bald and Golden Eagle Protection Act (BGEPA) (16 U.S.C. §§ 668–668c). A permit must be secured for any activities that might take or disturb eagles (50 C.F.R. §§ 22.1–22.32). The Grassland provides habitat for bald eagle and golden eagles persistence. The USFWS has developed national guidelines for managing bald eagles (USFWS 2007). The Forest Service must assess whether and how the proposed amendment might affect eagles.

Bald and golden eagles forage in prairie dog colonies. Prairie dogs are an important food source for golden eagles year-round in the Thunder Basin region and for bald eagles, particularly in winter (Stephens et al. 2005). Both species are known to hunt live prairie dogs and scavenge on dead prairie dog carcasses. Secondary poisoning from consuming poisoned prairie dogs (Rattner et al. 2015), lead poisoning from consuming prairie dogs shot with lead ammunition (Stephens et al. 2005; Pauli and Buskirk 2007) are threats to these species that will increase in risk with increased prairie dog poisoning and shooting on the Grassland. We note that the current Proposed Action indicates the amendment will not authorize anticoagulant poisons, which are known to pose a greater risk of secondary poisoning than other toxicants such as zinc phosphide (Scoping Document: 11). But the ingestion of zinc phosphide, a commonly used rodenticide used to exterminate prairie dogs, can negatively the health of eagles who feed on poisoned rodent carcasses (EPA 2004).

IX. Need for an assessment

We strongly suggest and specifically request that the Forest Service conduct an amendment assessment if it continues to go forward with the amendment process (FSH 1909.12, Ch. 10, § 15). The Scoping Document indicates the Forest Service has not availed itself of new information, particularly new scientific information, to sufficiently evaluate ecological and economic conditions and trends. The Forest Service has not completed a management plan monitoring report since 2012 for the year 2011, and, accordingly, the agency may not fully understand the conditions on the Grassland or possess best available scientific information (BASI) made available in the last 8 years or more.

We are particularly concerned that the Forest Service is proposing an amendment that presents an inappropriate management scheme for the existing ecological conditions on the Grassland. The Scoping Document emphasizes the expansion of “active” prairie dog colonies on and around the Grassland to 75,000 acres. The Forest Service describes this expansion as “more than doubling the previous record for mapped acres” (Scoping Document: 5) and appears to couch this as a problem the amendment is meant to solve. Yet, this expansion—48,000 acres of which occurred on the Grassland, with the remainder on private land—is within the natural range of variation for a prairie dog colony area, especially in the broader landscape context, and was predicted and expected by the Forest Service as outlined in the Biological Assessment and Evaluation (Appendix H) of the 2001 Northern Great Plains Management Plans Revision (USFS 2001). We are concerned the Forest Service does not recognize this.

Most importantly, 75,000 acres of prairie dogs ***is not*** the condition on the Grassland and broader landscape today. The Scoping Document points out that plague took a massive toll on prairie dogs in 2017, reducing active prairie dog colonies in and around Management Area 3.63 to about 1,000 acres, of which about 600 acres is on the Grassland. This is a condition that requires a very different management approach, one that focuses on recovering prairie dog populations to again be sufficient to support a viable ferret population. The Forest Service must assess the ecological effects of prairie dog losses to the landscape and effects on associated species to fill in knowledge gaps indicated by the proposed prescriptions in the Scoping Document and Proposed Action.

The Forests Service makes the following statement in the Scoping Document that the amendment is needed to "[e]nsure management direction identifies habitat requirements needed to support viable populations of prairie dogs and associated species …" (Scoping Document: 7). The statement demonstrates the Forest Service must assess the habitat requirements of these species.

The Forest Service must assess the economic conditions at play on the Grassland. The agency and the public must understand the past and recent trends in and projected costs of rodenticides purchases and use on the Grassland. What is the public interest benefit derived from the Forest Service's investment in this benefit to a private interest?

We urge the Forest Service to follow the guidance for assessments in the Planning Rule under 36 C.F.R. § 219.6(b) to conduct an amendment assessment of the following factors:

- The effects of the loss of prairie dogs to the terrestrial mixed-grass prairie ecosystem that dominates the Grassland and the species that depend on and benefit from prairie dogs as proposed by 36 C.F.R. § 219.6(b)(1) and (5) and associated guidance in the Planning Handbook. Prairie dogs are keystone species and benefit suites of species beyond prairie dog associate species and restore and maintain overall Grassland biodiversity. The Forest Service must assess the benefits of prairie dogs to the ecosystem and grassland species. Additionally, the Forest Service must examine the natural range of variation of occupied prairie dog colony area on the Grassland and the broader landscape.

- The effects of proposed management changes on the ability of prairie dog activity and fire to serve as keystone system disturbance processes—system drivers—on the Grassland proposed by 36 C.F.R. § 219.6(b)(3) and associated guidance in the Planning Handbook. Prairie dogs provide ecosystem services, such as soil moisture retention and improved forage quality and digestibility for livestock and native ungulates. But prairie dogs lose the ability to serve their essential ecosystem engineering role when population numbers and colony area are kept at artificially low levels. Additionally, fire is an essential disturbance process for the Great Plains grassland ecosystem. Proposed changes in management of these ecosystem drivers must be assessed.

- The effects of domesticated livestock as an ecosystem stressor and driver for the Grassland's dominant terrestrial ecosystem as proposed by 36 C.F.R. § 219.6(b)(3) and associated guidance in the Planning Handbook. We accept that livestock grazing will remain a use on the Grassland. But the Forest Service must take the BASI on this topic and assess the effects of livestock grazing on prairie dogs and associated and other species that benefit from prairie dog habitat. For example, Kohl et al. (2013) found that increased grazing and decreased movements by cattle combined with livestock stocking levels supported the hypothesis that current range practices are resulting in homogeneous grazing at a landscape scale and thus contributing to the decline of prairie-obligate species (see also Knopf 1996; Fuhlendorf et al. 2010). The importance of this ecological integrity issue (and also social issue)—prairie dog conservation and livestock grazing operations—to grassland management and conservation should necessitate a thorough scientific review of the literature on the ecological interactions between cattle and prairie dogs.

- A comprehensive assessment of the knowledge on competition and coexistence between cattle and prairie dogs. Prairie dogs can and do co-exist with cattle and contribute to healthy grasslands that provide forage for domestic livestock (see Sierra-Corona et al. 2015). The Forest Service must use the BASI to conduct an assessment that includes consideration of the benefits prairie dogs provide in coexistence with livestock.

X. Identifying and obtaining missing information

We previously requested the documentation the Forest Service relied upon to support several specific statements in the Scoping Document. We believe this information should be disclosed prior to the publication of the Draft EIS and renew our request the Forest Service to promptly make, at minimum, the following information available to the public:

- Roster of Interdisciplinary Team members.

- Documentation of the Forest Service's efforts to minimize impacts of prairie dog encroachment onto private and state lands, i.e., "the good neighbor policy." (see Scoping Document: 4)

- Documentation that prairie dogs are encroaching onto neighboring properties. (see Scoping Document: 4)

- The Forest Service stated in the Scoping Document that mapping efforts between 2015 and 2017 indicated 75,000 acres of active black-tailed prairie dog colonies existed in the vicinity of Management Area 3.63, of which 48,000 acres occurred on the Grassland. Documentation for the method used and the mapping results. (see Scoping Document: 5-6)

- Documentation of economic impacts to neighboring land values. (see Scoping Document: 2)

- Documentation of impacts to agricultural production. (see Scoping Document: 2)

- Best available scientific information documenting that Proposed Action 6b, "Active prairie dog colonies should be distributed across the landscape and vary in size, up to approximately 1,000 acres, with an emphasis on colonies of 100 to 400 acres" is sufficient to support a viable population of black-footed ferrets. (see Scoping Document: 11)

- Best available science documentation that managing for 7,500 acres of prairie dogs will support a viable population of black-footed ferrets, based on proposed Action 6c, "All prairie dog colony management tools not otherwise restricted by the plan will be available for use when the active acreage in management area 3.67 is greater than 7,500 acres." (see Scoping Document: 11)

XI. Conclusion

A thriving grassland ecosystem that maintains an abundance of wildlife and supports sustainable uses by the people who live adjacent to Wyoming's Thunder Basin National Grassland is possible. We believe this is a vision shared with the Forest Service, myriad stakeholders, and the American public who all have a voice for this Grassland. Unfortunately, the Forest Service's proposed amendment will steer away from this vision. It is likely to threaten the viability of prairie dogs and associated species that call the Grassland home. Further, it will not contribute to the recovery of the black-footed ferret.

The proposal's substantial removal of protections for prairie dogs will not change the issue of lack of implementation of the current plan, but it will lead to increased conflict on an issue that has been addressed previously and significantly in multiple public participation processes. The proposed amendment is likely to fail to comply with federal law, would preclude recovery for federally endangered black-footed ferret, and would put other imperiled species at an even greater risk of extinction. For these reasons, and the many others we outline above, we oppose the proposed amendment for Thunder Basin. We reiterate that the policy instruments the Forest Service believes it needs for "balance" remain available in the existing Management Plan.

Our organizations have dedicated substantial amounts of time and resources to promote the protection and recovery of the Grassland's wildlife, while respecting the Forest Service's multiple use mandate. We offer considerable expertise on relevant subjects to the proposed amendment, including black-tailed prairie dog and associated species conservation, black-footed ferret recovery, and national forest and grassland management planning. Given this, we would like to reiterate the following key comments:

- The Forest Service needs to comply with NFMA, National Environmental Policy Act, Endangered Species Act, the Migratory Bird Treaty Act, and the Bald and Golden Eagle Protection Act.
- Retain and fully implement the current plan, including the recovery and maintenance of prairie dog populations and associated species within Management Area 3.63 as it is essential in advancing recovery of the endangered black-footed ferret. Specifically, we request the Forest Service continue to manage toward a prairie dog complex of at least 18,000 acres of active prairie dog colonies in a contiguous area.
- Solutions to facilitating livestock and prairie dog coexistence must center on land uses and resource management activities that are conducted in a manner that is compatible with

maintaining suitable black-footed ferret habitat. Standards listed in the TBNG plan (Chapter 3, Management Area 3.63, General – 1 (revised)) include: 1) *Authorize only those uses and activities that do not reduce the suitability of the area as black-footed ferret reintroduction habitat*; and 2) *Manage all prairie dog colonies within this management area as though they were occupied by black-footed ferrets, and apply all Standards and Guidelines as though black-footed ferrets occur in all colonies*. And these standards must remain intact.

- Conduct annual monitoring of prairie dog populations and vegetation and employ the appropriate decision trees outlined in the current plan to adequately respond to changes that warrant a timely response.
- Repair communication, compromise, and trust among all Thunder Basin stakeholders by improving collaborative efforts that can transform social conflict and create sustainable solutions for people and wildlife. This could result in lasting outcomes related to prairie dog conservation and management on Thunder Basin National Grassland and enable an atmosphere of shared problem-solving that ultimately benefits both the people and wildlife living there.

Thank you for considering these comments. We submit them and associated information in the spirit of continued collaboration with the Forest Service and associated stakeholders of Thunder Basin, especially regarding ways we can contribute to a fuller implementation of the Management Plan, including the Black-tailed Prairie Dog Conservation Assessment and Strategy. We look forward to continuing to work with you on these complex management issues. If you have questions, please do not hesitate to contact us to discuss them.

Conservation of prairie dog ecosystem engineering may support arthropod beta and gamma diversity

R.K. Bangert*, C.N. Slobodchikoff

Department of Biological Sciences, Northern Arizona University, P. O. Box 5640, Flagstaff, AZ 86011-5640, USA

Received 17 November 2005; received in revised form 13 January 2006; accepted 19 January 2006

Abstract

Ecosystem engineering by animals can create new habitats and increase the heterogeneity of the habitat mosaic that in turn can increase plant and animal diversity. Prairie dogs in North America alter both the above- and below-ground structure of the landscape and create novel habitats in grassland ecosystems. The ground-dwelling arthropod community associated with Gunnison's prairie dog modified habitats is compositionally different from that found in the surrounding grassland. Individual arthropod families and species have different distributions in both active prairie dog towns and inactive towns, compared to unmodified grasslands. These different responses to ecosystem engineering increase beta (between-habitat) and gamma (regional) diversity. This study suggests that simple measures of alpha diversity (species richness) may not adequately quantify overall diversity and that measures of beta diversity may be necessary to assess the role of prairie dogs as keystone engineers. Thus, conservation of prairie dogs and the engineering process may have positive effects for numerous species both locally and regionally.

Keywords: Arthropod assemblage; Conservation; High desert grasslands; Ecosystem engineering; Gunnison's prairie dog; Keystone species; Petrified Forest National Park

1. Introduction

A critical issue in ecology is to determine the mechanisms behind the patterns of community assemblages. Once these mechanisms are better understood conservation

biologists will better be able to prioritize conservation efforts. Two relevant and important concepts in conservation theory are keystone species and ecosystem engineers (Lomolino and Smith, 2003). Keystone species confer inordinate effects relative to their abundance or provide unique services (Power et al., 1996; Kotliar, 2000). Ecosystem engineers modify their habitat and these modifications may have positive or negative effects on other species (Jones et al., 1997). Although the keystone concept can be contentious (Stapp, 1998; Miller et al., 2000), as more studies are published it is clear that ecosystem engineering can be one mechanism that confers keystone status to a species (e.g. Lomolino and Smith, 2003) through the impact that they have on ecosystems (Jones et al., 1994, 1997; Brown, 1995; Kotliar, 2000). These effects can have far-reaching consequences that can affect not only ecological associations, but also the behavior of animals within an ecosystem. For example, we have recently shown that keystone-engineering influences landscape structure, which then in turn affects animal movement behavior (Bangert and Slobodchikoff, 2000, 2004).

A major class of effects comes in the form of mechanical ecosystem engineering where an organism modifies or creates habitat through its activities (e.g. beaver; Wright et al., 2002). For example, the activities of pocket gophers can have ecosystem level effects that influence plant diversity at small scales (Huntly and Inouye, 1988; Martinsen et al., 1990) and influence the distribution of aspen at large scales (Cantor and Whitham, 1989). Other examples include leaf-modifying insects whose structures enhance richness and abundance of inquilines and other arthropods (Martinsen et al., 2000; Lill and Marquis, 2003), and kangaroo rat mounds that influence the distribution of arthropods and vertebrates (Hawkins and Nicoletto, 1992). If the ecosystem engineer is rare, its overall effect may be large relative to its biomass and therefore provides a unique ecological service and can be classified as a keystone species (Power et al., 1996; Kotliar, 2000). Consequently, ecosystem engineering can have important conservation consequences by creating a landscape mosaic that influences the structure of vertebrate communities and increases the richness of avian species of conservation concern (Lomolino and Smith, 2003; Smith and Lomolino, 2004).

Ecosystem engineering has been demonstrated for two species of prairie dogs (Sciuridae: *Cynomys* spp.) in North America (Weltzin et al., 1997a, b; Ceballos et al., 1999; Bangert and Slobodchikoff, 2000), but concerns have been raised about the strength of the evidence supporting prairie dogs as keystones based on species associations (Stapp, 1998). Although the effects prairie dogs have on soils and plants is well understood (Carlson and White, 1987; Whicker and Detling, 1988; Munn, 1993; Weltzin et al., 1997a, b), only recently has evidence for the relationship between prairie dogs and faunal communities been well documented (e.g. Lomolino and Smith, 2003; Smith and Lomolino, 2004). Previously most work has been conducted on the functional relationships between prairie dogs and a few charismatic vertebrates of concern (Knowles et al., 1982; Krueger, 1986; Clark et al., 1989; Oldemeyer et al., 1993; Desmond et al., 1995; Desmond and Savidge, 1996; Kotliar et al., 1999), and these studies have focused on associations with the black-tailed prairie dog, *C. ludovicianus*, in mixed and short grass prairie (but see Davidson et al., 1999). However, there are five species of prairie dogs that occupy a range of grassland habitat types in the western Great Plains and Intermountain West from Canada to Mexico (Goodwin, 1995; Hoogland, 1995, p. 12) potentially resulting in region-wide ecosystem engineering effects with large-scale conservation implications.

In this study, we investigate the relationship between the Gunnison's prairie dog (*C. gunnisoni*) and a grassland arthropod community, for three reasons. First, prairie dogs have significant above- and below-ground ecosystem level impacts (Vogel et al., 1973;

Carlson and White, 1987; Munn, 1993; Ceballos et al., 1999; Bangert and Slobodchikoff, 2000). Second, because arthropods represent over half of worldwide multi-cellular biodiversity (Crawford, 1981, 1991), arthropods are important ecosystem components (Seastedt, 1984; Kremen et al., 1993; Anderson, 1995; Parmelee, 1995), and little work has been done on the relationship between prairie dogs and arthropod communities (e.g. O'Meilia et al., 1982). Third, since prairie dog ecosystem engineering has been shown to have a positive effect on the richness and structure of vertebrate communities of conservation concern (Lomolino and Smith, 2003; Smith and Lomolino, 2004), it is important to quantify the relationship between prairie dog engineering and lower trophic levels. We use a comparative approach to take advantage of a natural experiment (sensu Diamond, 1986), and make the following predictions. Prairie dog habitat modification leads to: (1) differential responses by individual arthropod species to prairie dog-modified habitats; (2) this results in high beta (between habitat) diversity in arthropod community structure between prairie dog towns and unmodified grasslands; (3) high levels of beta diversity result in greater species richness across the landscape (gamma diversity).

2. Materials and methods

2.1. Study site

This work was conducted on the high desert grasslands (1600–1750 m above sea level) at Petrified Forest National Park (PEFO), Arizona, USA, during 1996 and 1997 from 1 June through 30 July. Petrified Forest has an average annual precipitation of 24.4 cm and average high temperatures ranging from 0.8 °C in January to 23.5 °C in July. Precipitation exhibits a single peak in July and August due to the summer monsoon. The vegetation at PEFO is characterized as shrub-steppe dominated by the large shrubs *Atriplex canescens*, *Artemisia filifolia*, and *Ar. Biglovii*, and the smaller *At. jonesii* and *At. confertifolia*. The grasses *Bouteloua gracilis*, *Stipa hymenoides,* and *Sporobolus* spp. are common (Kierstead, 1981).

2.2. The ecosystem engineer

The Gunnison's prairie dog (*Cynomys gunnisoni* Hollister) is a medium sized (675–1350 g) ground squirrel in the family Sciuridae. This species is found on the Colorado Plateau extending across four states in North America: Arizona, Colorado, New Mexico, and Utah (Fitzgerald et al., 1994; Goodwin, 1995). Gunnison's prairie dogs are colonial and social animals (Slobodchikoff, 1984; Hoffmeister, 1986; Fitzgerald et al., 1994), and prairie dog colonies, or towns, are conspicuous features of North American grassland ecosystems. Activities of prairie dogs include alteration of soil chemistry and extensive soil movement (Carlson and White, 1987; Munn, 1993; Ceballos et al., 1999), herbivory (Whicker and Detling, 1988), and granivory (Shalaway and Slobodchikoff, 1988), resulting in significant changes in the fractal dimension of landscape spatial structure and shrub distribution (Bangert and Slobodchikoff, 2000).

2.3. Experimental design

This study took advantage of a natural experiment (Diamond, 1986) where the landscape was manipulated by the Gunnison's prairie dog and 100% of the prairie dogs were extirpated from two of the five prairie dog towns by plague (*Yersina pestis*; Cully, 1989; Fitzgerald, 1993) 15 months prior to the beginning of this study resulting in a BACI-style experiment (B = before, A = after intervention, C = control, and I = Intervention; Stewart-Oaten et al., 1986, 1992). Natural experiments offer an important opportunity for study because it is both difficult and unethical to manipulate animals and landscapes at large scales, and this is particularly relevant to conservation studies (Farnsworth and Rosovsky, 1993; Brown, 1995; Lomolino and Smith, 2003). There were three levels of natural habitat variability in this study: (1) habitats with no modification by prairie dogs representing before and control effects (B and C; grasslands), (2) habitats previously modified by prairie dogs but with no prairie dogs present representing the after intervention effect (A; inactive towns), and (3) habitats with prairie dogs present (active towns) represent the intervention (I) aspects of a BACI-type experimental design.

In 1996 three active prairie dog towns, two inactive prairie dog towns, and five grassland habitats were sampled for ground-dwelling arthropods. One active site and a nearby grassland site were sampled concurrently for five consecutive days, and then an inactive site and another grassland site were sampled concurrently. Additional active, inactive, and grassland sites were alternately sampled in order to reduce temporal pseudoreplication (Hurlbert, 1984) resulting in a total of 2500 trap days. Each grassland site was <1 km from the nearest prairie dog town. In 1997 access to towns was restricted because of archeological concerns, so increased effort was concentrated at one active town, one inactive town, and a grassland site located approximately 6 km in-between the two prairie dog towns. All three sites were sampled concurrently for 19 days resulting in 2850 trap days. During both years 50 pitfall traps were distributed randomly over 1 ha at each site. Arthropods were identified to family, and we feel that this provides good resolution and a conservative approach for this study. For example, at the family level most species can be categorized by trophic status, with the exception of the ants (Formicidae).

Traps were 12 oz. Solo® plastic cups nested in 16 oz. cups set flush with the ground surface. Each trap had an elevated plywood lid for shade (900 cm^2) to protect animals from the sun. Each morning, traps were checked, arthropod identification was determined to family level and the arthropods were counted and then released in a random direction ≈ 3 m from the trap. Large mobile animals were marked with a unique number to avoid recounting. Animals not identified to family were collected for later identification and "Day" was the sample unit used in the composition analysis. Since all traps in 1997 were sampled concurrently, we checked for temporal autocorrelation by examining residuals and the Durbin–Watson test indicating that there was no autocorrelation between days and therefore days were regarded as independent. Every site was subjected to the same sampling regime and the weather was consistent throughout the sampling period from 1 June through 30 July within each year. In 1997 the distance from each trap was quantified to the nearest burrow to assess the arthropod relationship with burrows.

2.4. *Differential effects of above-ground engineering*

2.4.1. *Unique taxa*

Ecosystem engineering hypotheses predict that some species will be positively affected and some negatively affected by mechanical engineering and subsequent habitat alteration

(Jones et al., 1997). First, the number of unique taxa associated with prairie dog towns was quantified. Prairie dog towns were nested within the larger grassland landscape matrix of $\approx$37,851 ha (we estimated that prairie dog towns comprise $<$2% of the landscape area at PEFO). Therefore the null expectation was that the faunas associated with prairie dog towns would also be nested within the overall grassland arthropod family pool. To address this, the proportion of unique families contributed by individual prairie dog towns was assessed with single sample *t*-tests. Individual towns were compared to grasslands at three different scales: (1) versus the nearest grassland site of the same size, (2) versus all grassland sites pooled within the year that the prairie dog site was sampled, and (3) versus all grassland sites pooled across years. This resulted in a test that was increasingly biased in favor of the grassland family pool as grassland scale increased. For this analysis active and inactive towns were considered as the same treatment, resulting in seven replicate prairie dog towns. Under the null hypothesis that the prairie dog arthropod community is a perfectly nested subset of the larger regional grassland family pool, the proportion of unique families found on prairie dog habitats should be zero.

2.4.2. Indicator taxa

The occurrence of indicator taxa for each habitat was quantified with the software program INDVAL (Dufrêne and Legendre, 1997). Indicator taxa are determined by the distribution of individuals within each taxon across samples and treatments. The indicator value, *I*, indicates the percent predictability of sampling a particular taxon in a particular habitat type with *p*-values determined by Monte Carlo methods. For example, if ants were found in all samples within only one habitat type they would have an indicator value of $I = 100.00$ for that habitat.

In order to assess the effects of above-ground engineering on community structure, the 1996 arthropod community was quantified at each site ($n = 10$) with nonmetric multidimensional scaling (NMDS; Minchin, 1987, 1999) and the community one-dimensional solution ordination scores were regressed against the fractal dimension of each site (Anderson, 2001). Landscape fractal dimension was used as a measure of ecosystem engineering, where sites with large fractal dimensions were associated with heavily modified prairie dog habitats (Bangert and Slobodchikoff, 2000).

2.5. Relationship with below-ground structures

To assess the effects of below ground engineering, i.e. burrows, in 1997 we modeled the distribution of two abundant beetle species in the family Tenebrionidae and crickets in the family Gryllacrididae, and their relationship to prairie dog burrow proximity with loglinear regression (Agresti, 1996). In 1998, traps were placed at 1 and 5 m from burrow entrances. Pairs of traps were placed at random at a grassland site and randomly designated as the "1 m" or "5 m" traps. This was done because adding a burrow treatment to a grassland site was not permitted because of archaeological concerns in the Park. Additionally, at the community level Mantel tests were used to assess the relationship between abundance and community structure with distance from burrows. If burrows do not influence these animals, the null hypothesis predicts that traps at all distances from burrows will trap similar numbers of animals and have similar communities.

2.6. Community structure

In this study we concentrate on beta diversity (community structure between habitats) because alpha diversities (e.g. species richness between habitats) may not be different but community structure can be very different (Bangert et al., 2005; Wimp et al., 2005). Beta diversity was assessed as dissimilarity in community structure between habitats, and was quantified with the powerful ordination technique, Canonical Analysis of Principal coordinates (CAP; Anderson and Willis, 2003) and the Bray–Curtis similarity coefficient (Bray and Curtis, 1957; Kruskal, 1964; Faith et al., 1987; Minchin, 1987; Clarke, 1993; Legendre and Legendre, 1998; Dungey et al., 2000). Additionally, pairwise comparisons were conducted between all treatments and randomization tests were used to determine *p*-values. These *p*-values are reported without any correction for multiple tests so that readers can make their own determination as to the strength of the treatment effects. CAP is appropriate for these data because the procedure corrects for the effect of taxa that are correlated across treatments. Finally, we use accumulation curves to assess the contribution of the prairie dog treatments to gamma, i.e. regional diversity.

3. Results

3.1. Differential effects of above-ground engineering

3.1.1. Unique taxa

Unique families were found in both prairie dog and grassland habitats. Prairie dog and grassland habitats contributed 6 and 10 unique families, respectively. Even though there were not consistent differences in richness between individual prairie dog towns and the nearest grassland site, at all scales prairie dog towns contributed more unique taxa than expected by chance if they were simple subsets of the grassland family pool (vs. nearest grassland: $t = 6.78$, df = 6; $p = 0.0005$; vs. grasslands pooled within year: $t = 4.15$, df = 6; $p = 0.003$; vs. all grasslands pooled across years: $t = 1.91$, df = 6; $p = 0.053$; Fig. 1a). For example, the 1997 ordered accumulation curve shows that prairie dog-modified habitats contribute families beyond the families found on grassland habitats even though there were no differences in richness among treatments (Fig. 1b; the 1996 accumulation curve was similar to the 1997 curve). These data suggest that prairie dog activities significantly affect this ground-dwelling arthropod community at different scales, and the quantification of beta diversity is as informative as alpha diversity (Su et al., 2004).

3.1.2. Indicator taxa

There were several families that were significant indicators for each of the three habitat types in this study. The response by different families to different habitats was what might be expected. For example, the insect herbivore family, Cicadellidae, was almost 10 times more abundant on grasslands relative to prairie dog habitats ($z = 4.50$, $p < 0.0001$), while the Scarabaeidae was 13 times more abundant on active prairie dog towns where scats were abundant ($z = 3.09$, $p = 0.001$). Indicator value analysis suggests that over the course of this study, Cicadellidae were the only significant indicators of grasslands. Pholcidae, Mutillidae, Curculionidae, Cerambicidae, and Isopoda were significant indicators of inactive towns, and Salticidae, Gelichiidae, and Gryllidae were significant indicators of

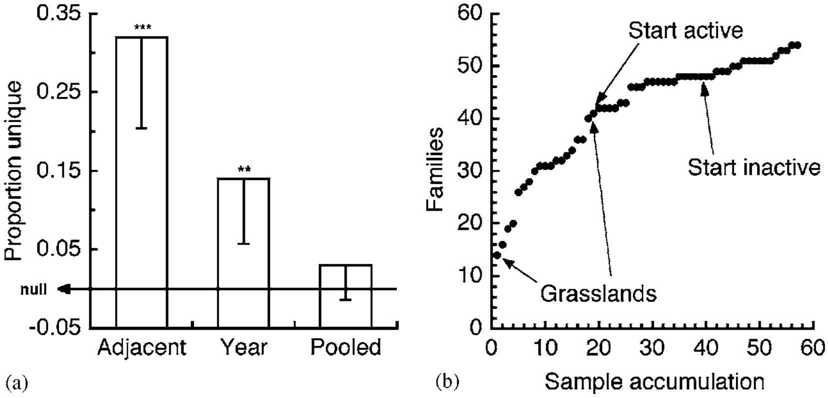

Fig. 1. (a) Mean proportion of unique families contributed to the grassland ecosystem by seven prairie dog towns at different scales. One-sample *t*-tests of these proportions on individual prairie dog towns versus the null hypothesis that prairie dog habitats are subsets of the greater grassland ecosystem with the proportion of unique families equal to zero. "Adjacent" is individual towns versus the nearest grassland site, "Year" is individual towns versus all grassland communities pooled for that year, and "Overall" is individual towns versus all grassland communities pooled across years, resulting in an increased bias, in favor of the null hypothesis, as grassland scale increases. Horizontal line represents the null hypothesis. Error bars represent the lower 95% confidence interval, two asterisks indicates significance at $p<0.01$, and three asrterisks indicate $p<0.001$. (b) 1997 ordered accumulation curve (grasslands-active-inactive) of family richness where all three habitats had similar numbers of families, but active and inactive towns add unique families beyond what the grasslands contribute. The 1996 accumulation curve is similar to the 1997 accumulation curve.

Table 1
Arthropod families that were significant indicators of habitat types on the grasslands at Petrified Forest National Park, AZ, USA

	Active		Inactive		Grasslands		Functional group
Family	IndVal	*t*-value	IndVal	*t*-value	IndVal	*t*-value	
Salticidae	19.2	3.24					Predator
Gryllidae	16.6	4.18					Herbivore
Gelechiidae	18.1	4.86					Herbivore
Pholcidae			43.9	4.43			Predator
Isopoda			21.4	4.20			Omnivore
Cerambicidae			24.7	5.53			Herbivore
Curculionidae			26.5	2.90			Herbivore
Mutillidae			43.2	4.84			Parasitoid
Cicadellidae					32.0	5.58	Herbivore

active towns (Table 1). This analysis supports the hypothesis that different taxa respond differently to prairie dog engineering and this results in high arthropod beta diversity.

3.2. Relationship with below-ground structures

There was a relationship between below ground engineering (burrows) and three conspicuous taxa. The beetle *Eleodes extricata* had greater numbers on the inactive than

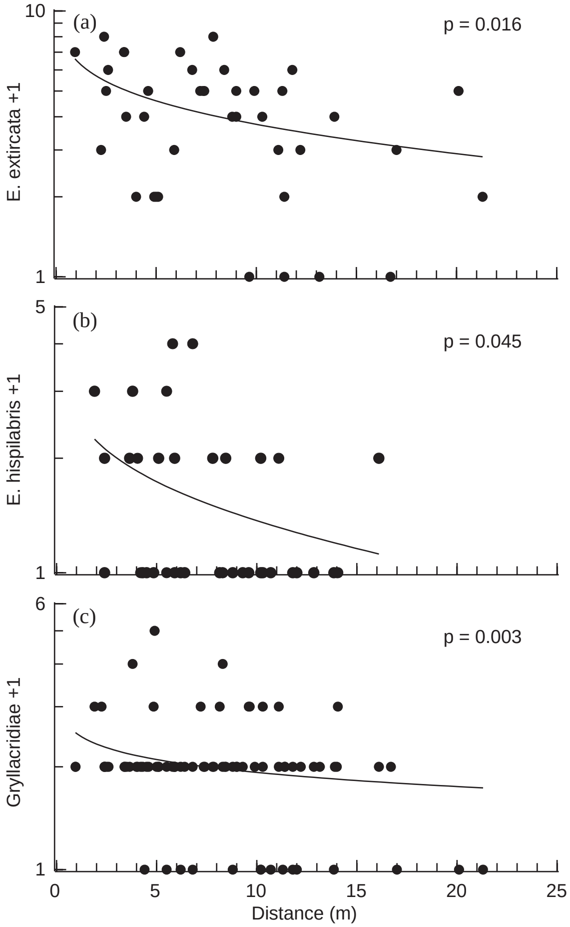

Fig. 2. Beetle and cricket correlations with prairie dog burrows modeled with loglinear regression. *E. extricata* was trapped more often closer to burrows on an inactive prairie dog town (a). *E. hispilabris* (b) and camel crickets (c) were trapped more often closer to burrows on both active and inactive towns.

active town (df = 1, $\chi^2 = 36.6$, $p < 0.0001$) and was trapped more often in close proximity to inactive prairie dog burrows (log beetle = 1.673–0.046 × distance, $p = 0.01$, Fig. 2a). *E. hispilabris* had equal numbers between both prairie dog habitats and was trapped closer to all burrows types (log beetle = 0.492–0.023 × distance, $p = 0.045$, Fig. 2b). Gryllacridid crickets were also trapped more often closer to all burrow types (log cricket = 0.86–0.27 × distance, $p = 0.003$, Fig. 2c). In 1998 trapping frequencies for these three taxa were evaluated at 1 and 5 m from burrow entrances, and in pairs of traps on a grassland site. There were no crickets trapped on the grassland and 233% more crickets trapped in the 1 m traps than in the 5 m traps ($\chi^2 = 29.6$; $p = 0.0001$; df = 2). Likewise, there was only one beetle trapped on the grassland site and 135% more beetles trapped at 1 m than at 5 m from burrow entrances ($\chi^2 = 26.3$; $p = 0.0001$; df = 2). These data suggest that burrows are important to these animals.

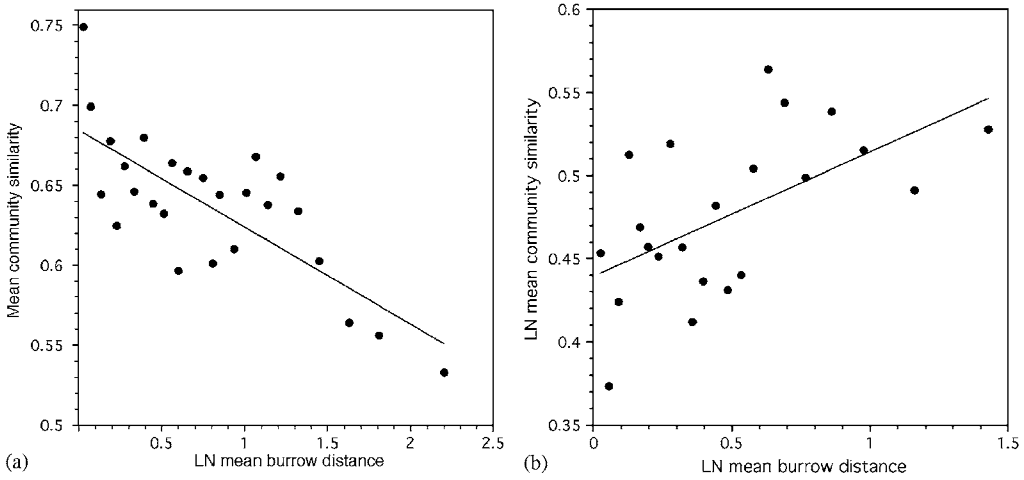

Fig. 3. Arthropod communities are more similar closer to burrows, on average, at the inactive prairie dog town (a), but show the opposite response at the active town where communities are more similar at greater distances from burrows (b). Community similarity is represented by the Bray–Curtis similarity coefficient and similarity in burrow distance is represented by Euclidean distance, where small distances represent communities that are more similar.

Community structure was similar at similar distances from burrows on the inactive town (Mantel $r = -0.3146$, Mantel $t = -3.44$, $p = 0.0003$, $n = 26$; Fig. 3a), and the pattern was opposite on the active town (Mantel $r = 0.1897$, Mantel $t = 1.91$, $p = 0.03$, $n = 22$; Fig. 3b). In other words, community structure changes with proximity to burrows differently between these two habitats, which suggests that there may be differences in burrow environments between active and inactive towns resulting in a habitat mosaic that increases beta diversity.

The above-ground engineering component showed that 22 families had significantly greater relative abundances among the three different habitats, but these were equally distributed (active = 8; inactive = 7, grass = 7), suggesting that alpha diversity alone is not sufficient to characterize differences between treatments. This analysis also supports the hypothesis that ecosystem engineering affects taxa differently. Overall, 68% of these families showed a positive response to prairie dog engineered landscapes, inactive and active combined. At the community level habitats with similar landscape structures, measured by fractal dimension, had similar arthropod community structures ($r^2 = 0.4849$, $p = 0.025$, $F_{1,8} = 7.53$; Fig. 4).

3.3. Community structure

Over 2 years of this study, 2315 arthropod individuals were distributed over 68 families in 5350 trap days. There were differences in community structure by habitat and a Canonical Analysis of Principal coordinates (CAP; Anderson and Willis, 2003) indicated that the arthropod community in each habitat was unique (1996: all pairwise $p \leqslant 0.002$, Fig. 5a; 1997: all pairwise $p \leqslant 0.0002$, Fig. 5b).

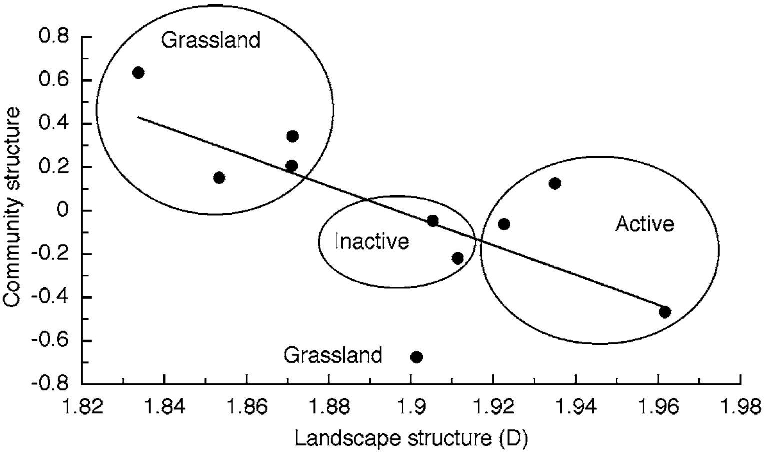

Fig. 4. Arthropod community structure at each site (1996) changes with an increase in prairie dog engineering. The mean landscape fractal dimension of each site is a measure of engineering, where large fractal dimension indicates more intensive prairie dog activity. Arthropod community structure is based on the one-dimensional NMDS ordination scores, which place a multivariate community into one-dimensional Euclidean space with no a priori expectation on the slope of the relationship, but rather, community composition changes with engineering. Site treatments are encompassed by ellipses.

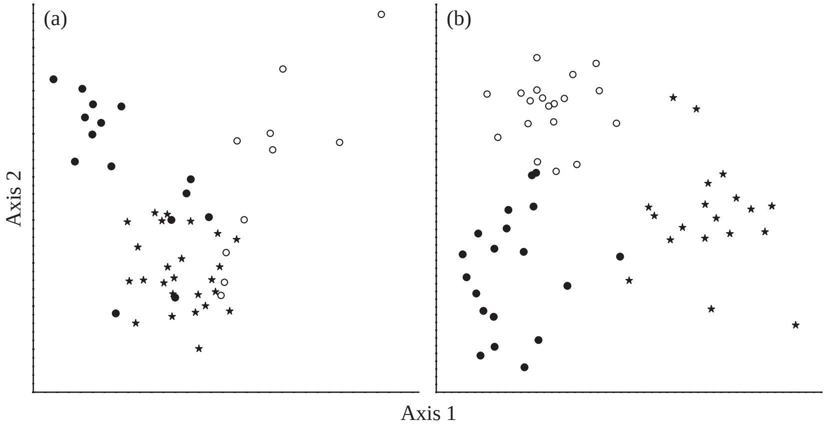

Fig. 5. Canonical analysis of principal coordinates (CAP) of community composition where axes are unit-less and only serve to place points in ordination space; points close together are more similar than points that are more distant. (a) Arthropod community structure at 10 sites × 5 days for 1996, and (b) for the 3 sites × 19 days in 1997. In both years the communities are significantly dissimilar across the three treatments. Active = ●; Inactive = ○; Grasslands = ★.

4. Discussion

This is the first community-level study that examined the effects of ecosystem engineering by the Gunnison’s prairie dog on arthropods, comparing active and inactive prairie dog towns with unmodified grasslands. In this study both above- and below-ground prairie dog engineering was significantly correlated with several arthropod species, and with community structures between each prairie dog habitat and the grassland matrix. The high beta diversity associated with the presence of prairie dogs resulted in an increase in gamma diversity within Petrified Forest National Park. For example, family richness was the same for the three habitats and yet an analysis of community structure indicated that there were distinct communities associated with the three habitat types in this study. High beta diversity is likely due to individual responses by different taxa to prairie dog engineering as predicted by one ecosystem engineering hypothesis (Jones et al., 1997). For example, prairie dogs may be contributing detritus (see Hawkins and Nicoletto 1992 with reference to kangaroo rat contribution of detritus), thus detritivores (e.g. Scarabaeidae rolling scats, pers. obs.) may become more abundant in prairie dog modified habitats, whereas herbivory by prairie dogs may exclude insect herbivores such as the Cicadellidae in the active towns. We found that there were a significant proportion of unique families associated with both types of prairie dog habitats over a large range of scales. Thus, without prairie dogs there would be no beta diversity component and gamma diversity would likely be 33% lower (Fig. 1b). On the high desert grasslands of Petrified Forest, prairie dog engineering appears to create a habitat mosaic that significantly influences the arthropod community at several scales. This suggests that prairie dogs play a unique role in this desert grassland ecosystem and therefore, they may be a keystone to this faunal community (e.g. Kotliar, 2000). We expect that if a finer resolution of taxa were used, e.g. the species level, these patterns would become stronger.

We used the fractal dimension of landscape structure as a measure of above-ground ecosystem engineering (Bangert and Slobodchikoff, 2000) and found that sites with similar levels of ecosystem engineering also had similar community structures. An alternative hypothesis is that the presence of prairie dogs on the active town inhibits arthropod activity. We do not favor this hypothesis because insects are not a significant component of prairie dog diets (Fagerstone et al., 1981; Shalaway and Slobodchikoff, 1988). Another alternative hypothesis is that arthropods are responding to changes in floristic structure due to prairie dog activities; however, we did not test this hypothesis, although, changes in floristic structure have been shown to result from prairie dog engineering activities (Archer et al., 1987; Whicker and Detling, 1988, 1993; Weltzin et al., 1997a, b).

Because there were different responses to burrows among arthropod species and communities between the active and inactive towns, this suggests that there may be differences in burrow environments between these towns (see Hawkins and Nicoletto). One hypothesis is that burrows on the active town are maintained in an open condition facilitating burrow self-ventilation resulting in lower levels of relative humidity (Vogel et al., 1973), potentially affecting arthropod osmoregulation (e.g. Riddle et al., 1976; Slobodchikoff, 1983; Whicker and Tracy, 1987; Parmenter et al., 1989), whereas the burrow entrances on inactive towns become closed with time (pers. obs.) thus inhibiting the ventilation process, resulting in a more equable environment (e.g. Schmidt-Nielson and Schmidt-Nielson, 1950).

The above- and below-ground results support the hypothesis that ecosystem engineering by the Gunnison's prairie dog provides a unique ecological service (Kotliar, 2000) that may enhance arthropod diversity. These results do not suggest that we can eliminate prairie dogs in order to create inactive town habitats, but rather support the hypothesis that prairie dog engineering results in a mosaic of habitat conditions, i.e. landscape heterogeneity, that increase beta and gamma diversity (e.g. active habitats also contain unique species). All species of prairie dogs are suffering dramatic population declines due to human activities, persecution, and the exotic epizootic plague, *Y. pestis* (Miller and Cully, 2001). Thus, prairie dogs require conservation attention and consideration as threatened species, as well as their importance in creating habitat mosaics that are important to many invertebrate and vertebrate species (Lomolino and Smith, 2003).

Prairie dog towns are important to many vertebrate species of concern (e.g. black-footed ferrets, bald eagles, ferruginous hawks, and burrowing owls) and influence mammal, herptile, and avian community structure (Lomolino and Smith, 2003; Smith and Lomolino, 2004). This is the first community level study to demonstrate that prairie dog habitats are also important to invertebrates. This is of conservation concern because the diversity of animals at the base of the food web has the potential for a bottom-up contribution to ecosystem function, and the diversity of taxa at higher levels may be mediated by prairie dog engineering. For example, other studies have found higher abundance of small mammals (O'Meilia et al., 1982; Agnew et al., 1986, 1988), significant differences in mammal community structure, and higher diversity of vertebrate species of conservation concern (Lomolino and Smith, 2003; Smith and Lomolino, 2004) on black-tailed prairie dog towns compared to adjacent grasslands. Most of the species in these studies incorporate arthropods in their diet and this provides the testable hypothesis that diversity at lower trophic levels, i.e. invertebrates, may positively affect diversity at higher trophic levels, i.e. vertebrates, on prairie dog towns. One mechanism for greater vertebrate diversity may be due to high arthropod beta diversity, resulting in a more heterogeneous feeding niche space for vertebrate insectivores.

The prairie dogs' influence on soils and plants (Carlson and White, 1987; Whicker and Detling, 1988, 1993; Munn, 1993) should be sufficient to classify prairie dogs as keystone species. This study is consistent with the hypothesis that prairie dogs may be keystone species to animal communities as a result of their engineering activities (Ceballos et al., 1999; Kotliar et al., 1999; Kotliar, 2000; Miller et al., 2000). As in the grasslands of the Great Plains, the continued loss of prairie dog habitat and the homogenization of this high desert grassland will result in the decline of arthropod diversity, and potentially vertebrate diversity, similar to that described by Lomolino and Smith (2003). This adds support to the more holistic approach of habitat conservation as a more efficient conservation strategy (e.g. Bangert et al., 2005) through the protection of these ecosystem engineers (e.g. Simberloff, 1998) and their extended effects (Smith and Lomolino, 2004), rather than a continuation of the practice of conservation triage where numerous species become threatened due to the loss of the habitat mosaic created and maintained by this class of organisms.

Acknowledgements

We would like to thank J. Bailey, G.D. Martinsen, V.J. Meretsky, P.W. Price, J.A. Schweitzer, J.A. Smallwood, D.M. Wagner, G.M. Wimp, and several anonymous reviewers for helpful comments on previous drafts of this paper. We appreciate the efforts of M. Hellickson, W. Grether, and M. DePoy at Petrified Forest National Park for encouraging and facilitating ecological work in the Park and J.C. Soborio for help with arthropod identification. This work was in part funded by grants provided by the Petrified Forest Museum Association to RKB.

Introduction

Prairie dog colonies once stretched from southern Canada to northern Mexico, east of the Rocky Mountains (Hall 1981). Prairie dogs affect many ecosystem processes (Detling and Whicker 1987) and studies have suggested that prairie dogs are important for the maintenance of biodiversity in grasslands (Miller et al. 1994, Reading and Matchett 1997), increasing species richness or abundance of plants (Bonham and Lerwick 1976, Whicker and Detling 1988), arthropods (Agnew et al. 1987), and vertebrates (Agnew et al. 1986, Barko 1996, Ceballos et al. 1999).

Historically, prairie dogs were the target of widespread eradication programs (Anderson et al. 1986, Miller et al. 1996), which, along with land conversion, led to decline of the species to less than 2% of its original range, by conservative estimates (Miller et al. 1994, Mulhern and Knowles 1995). Competition between livestock and prairie dogs for forage has long been the justification for eradication programs (Collins et al. 1984). However, O'Melia et al. (1982) found no significant difference in weight gain between steers that grazed on or off prairie dog colonies. In fact, facilitation in the form of enhancement of forage quality for, and preferential grazing by, pronghorns (Krueger 1986), bison (Coppock et al. 1983b, Krueger 1986) and domestic cattle (Knowles 1986) have been shown for prairie dog colonies relative to uncolonized mixed grass prairie. Despite the obvious reduction in above-ground biomass available for grazers caused by prairie dogs (Coppock et al. 1983a), ungulates seek out prairie dog colonies to forage (Whicker and Detling 1988). The advantage to grazers comes in the form of enhanced crude protein (nitrogen) content of the newly regrowing shoots of previously clipped vegetation (Detling and Whicker 1987, Sharps and Uresk 1990). Likewise, prairie dogs may maintain an herbaceous cover in grasslands and prevent encroachment of woody species, improving rangelands for other grazers (Weltzin et al. 1997a, Weltzin et al. 1997b).

Natural History

Morphological Description

Black-tailed prairie dogs (*Cynomys ludovicianus*) are robust, stockily built ground squirrels. These animals are usually a buff brown with a grizzled black appearance (Figure 1). The last third of the tail is black tipped and 7-10 cm long. Adult *C. ludovicianus* usually weigh 0.8-1.5kg and reach a length of 31-41cm (including the tail; Clark and Stromberg 1987). The head is broad and rounded with relatively large eyes and small ears. The legs are short and powerful, each foot having 5 digits with well-developed claws for digging. The skull characteristics of black-tailed prairie dogs are described by Hoogland (1996) and Hall (1981), but in general the skull is broad and angular with large processes (Figure 2). Their body pelage molts seasonally (twice yearly; Hoogland 1996) and is different between age and sex groups. The first to undergo the molt are the non-breeding juveniles, second are the non-breeding adults, third are the breeding males, and last are the breeding females (Hoogland 1995). It is thought that this sequence of molting is related to the overall body condition, with the most “fit” individuals molting first (Hoogland 1995). Juveniles undergo a “post-juvenile” molt starting at the rump and extending anteriorly (Smith 1967). Contrastingly, adults will molt posteriorly from the head every October. Males and females will also exhibit a differential molt, with the genitalia and secondary sexual characters molting soon after the head (Smith 1967). The color pattern on individual hairs differs during the respective molt period (Hoogland 1996).

All five species of prairie dogs (see Taxonomy) are similar in morphology and appearance, but since the species’ ranges do not overlap, locality is diagnostic (see below; Hoogland 1995).

Taxonomy and Distribution

Taxonomy

The complete taxonomic classification for the black-tailed prairie dog is as follows (Hoogland 1996): Order: *Rodentia,* Suborder: *Sciurognathi,* Family: *Sciuridae,* Subfamily: *Sciurinae,* Tribe: *Cynomyini,* Subtribe: *Spermophilina,* Genus: *Cynomys,* Subgenus: *Cynomys,* Species: *ludovicianus.* Two subspecies of black-tailed prairie dogs are recognized: *C. l. arizonensis* located in the southern portion of the black-tailed prairie dog range and *C. l. ludovicianus* located in the northern part of the black-tailed prairie dog range (Hall 1981; Hoogland 1996). Black-tailed prairie dogs are one of five species in the genus *Cynomys*, in the family *Sciuridae*. Mexican prairie dogs (*C. mexicanus*) are the closest relative to black-tailed prairie dogs but do not overlap in range. White tailed prairie dogs (*C. leucurus*) and Gunnison's prairie dogs (*C. gunnisoni*) are found in intermountain basins of the rocky mountain west (Clark 1987). Utah prairie dogs (*C. parvidens*) are found in short-grass prairies of southwestern Utah and are more closely related to white tailed prairie dogs (Hoogland 1996).

Interestingly, the prairie dog was originally named the "Louisiana marmot" (*Arctomys ludovicianus*) by Ord in 1815 due to its outward resemblance to a marmot, but the name was changed to the current genus *Cynomys* in 1817 by Rafinesque (Smith 1967).

Distribution

Black-tails are the most widely distributed species of prairie dog (Figure 3), thought to once occur from southern Canada to northern Mexico, covering a continuous 400-mile wide band from the foothills of the Rockies to the central lowlands of the Great Plains (Koford 1958, Hall 1981). Currently, this species still occurs over its entire range (except Arizona) in small, fragmented colonies (VanPutten and Miller 1999). Generally, *C. ludovicianus* occur east of the other four prairie dogs in North America, occupying more mesic habitats.

In Wyoming, the distribution of prairie dogs is restricted to the eastern third of the state, where short and mixed grass prairies dominate the landscape (Figure 4). The western extent of this range is not well defined, and there may be a zone of sympatry between *C. ludovicianus* and *C. leucurus*, which occupy the sage-grassland basins in central and western Wyoming. There is only one documented occurrence of a stable black-tailed prairie dog colony west of this area, in the Bighorn Basin. Since this colony is so far from the main range of black-tails and is located along a main highway, it likely represents an artificial, anthropogenic introduction rather than a legitimate range expansion (D. Keinath, personal communication).

Recently the Wyoming Game and Fish Department (WGFD) in cooperation with the Wyoming Bureau of Land Management (BLM) have completed a digital map of *C. ludovicianus* towns in Wyoming using 2002 aerial photographs. The portion of this map that represents active towns is unknown, since no estimate of activity has been assessed for the digitized towns. In addition, the map is incomplete since 1/3 of the photographs were unable to be digitized. In fall 2005, the map should be available on the Wyoming Natural Diversity Database (WYNDD) website (http://uwadmnweb.uwyo.edu/wyndd) after it has been evaluated and the quality of the map can be reported (D. Keinath, personal communication).

Habitat Requirements

General

Black-tailed prairie dogs are thought to have once covered the entirety of the Great Plains grasslands (Hall 1981, Miller et al. 1994) (Figure 5). Short- and mixed-grass prairies are easily colonized by prairie dogs especially when the range is overgrazed or in poor condition (Koford 1958). Tall-grass prairie appears to be difficult for prairie dogs to inhabit (Allan and Osborn 1954), possibly because the high levels of vegetative production interfere with clipping, a behavior used by prairie dogs to lower overall vegetative height, facilitating predator detection. Fine, non-sandy soils seem to be important for burrow construction (Clippinger 1989, Reading and Matchett 1997) and may influence the distribution of prairie dogs. Shrubby areas are less favorable for colony establishment, but may not inhibit expansion of existing colonies (Weltzin et al. 1997a). Gently sloping areas (0-10 degrees) are preferred and slopes over 20 degrees are rarely used in the establishment of new colonies (Clippinger 1989, Reading and Matchett 1997). *Cynomys ludovicianus* is rarely found above 2,377m and usually found below 1,829m (May 2004). Black-tailed prairie dogs do not require open water (Clippinger 1989) because of a specialized kidney physiology (Harlow and Menkens 1986) that allows them to more efficiently use water obtained from plants. There is no seasonal variation in habitat requirements due to the colonial nature of this species; therefore, the breeding, foraging, and over-wintering habitats are similar (Hoogland 1995).

A habitat suitability index (H.S.I.) model was completed in 1989 for black-tailed prairie dogs by the USFWS (Clippinger 1989). Models, such as the one developed by Clippinger (1989), have identified important habitat attributes for the species of interest. The habitat attributes considered by Clippinger (1989) were availability of food, water, cover, and soil type. His conclusions about food was that suitable habitat must contain sufficient grasses for spring and summer consumption, a forb flora which will be utilized in fall, and adequate prickly pear available for water needs during winter. According to Clippinger (1989), the food component of the H.S.I. model needs to be a minimum of 15% herbaceous cover for continuous habitation by prairie dogs. For the cover component, vegetative height levels of 5cm to 20cm are considered optimal with a slope of less than 10 degrees for burrow establishment. The cover values are considered to be the most critical component of the model by Clippinger (1989). Soil type is also considered, and has a broad spectrum of acceptable soil types for burrow establishment. Clippinger's (1989) H.S.I. equation is the following:

$$(V_1 \times V_2 \times V_3 \times V_4)^{1/4} = H.S.I.$$

Where: V_1= % herbaceous cover, V_2= slope, V_3= vegetative height, and V_4= soil type

In Wyoming, short-grass prairies in the southeast along with mixed-grass prairies through the northeast compose the majority of habitat for *C. ludovicianus* (Figure 4). The productive, gently rolling hills of the eastern third of the state provide the necessary habitat for colony establishment. The climate in Wyoming is favorable for year round activity, and provides a plant species composition and productivity comparable to that of the nationwide range.

Area Requirements

Coteries, the smallest family unit of a colony or town, are on average 0.3 ha in size, but can range from 0.05 ha to 1.0 ha in size (Hoogland 1995). In theory, the smallest possible unit of area prairie dogs could colonize would be the area of land needed for one breeding pair or family unit which would be ~ 0.05 ha. In Colorado, studies indicated that *C. ludovicianus* colony sizes ranged from one acre to 4,129 acres, with an average size of 75acres; however, most colonies were 1 – 20 acres in size (see May 2004).

Landscape Pattern

The general landscape pattern needed for continous habitation of black tailed prairie dogs is typified by the gently rolling topography and abundant forage of the Great Plains. Shrub dominanted landscapes can also be colonized, but are less preferred to open habitats of grasses and forbs (Clippinger 1989).

Movement and Activity Patterns

Dispersal

The most common movement of this species is of minimal distance due to its colonial nature. However, long distance dispersal does occur, but is very difficult to track (Hoogland 1995) and seems to be rarely successful due to predation risk away from the colony. A study conducted on intercolonial dispersal by Garrett and Franklin (1988) found that dispersal distances can be as much as 5 km. They also found that prairie dogs rarely disperse to start a new colony, rather they move to another established colony. The most common time for dispersal to occur is about a month or so after the juveniles have emerged for the year (Hoogland 1995).

The ultimate cause of dispersal from the natal breeding sites is to prevent inbreeding (Felhamer et al. 2004). Within *C. ludovicianus* populations, young males leave the family group before breeding, whereas females remain. In addition, adult males usually leave groups before their daughters mature (Hoogland 1982). Immigration and emigration by yearling males can be important for gene flow (outbreeding) in large complexes of black-tailed prairie dogs if dispersal is across mostly colonized area (Hoogland 1995).

Impediments to dispersal are largely centered on predation risk. Black-tailed prairie dogs heavily rely on the alarm calling actions of nearby vigilant conspecifics (Hoogland 1981), and a low degree of visual obstruction to detect danger. When venturing into uncolonized, unclipped territory, the danger of predation increases (Hoogland 1995). As a result, most adult and some juvenile male dispersal is within his home colony, although not near his home coterie. Long distance dispersal, when it occurs, is most commonly associated with juvenile rather than adult males, and is usually solitary rather than group movements. Male dispersal peaks during a postweaning period (June – August; Roach et al. 2001). Dispersal of juvenile females is very uncommon because they usually stay and breed on the home coterie for life. If dispersal does occur with a female prairie dog, it is almost always long distance dispersal to another established colony (Hoogland 1995). Other barriers to movement are few, but include large bodies of water such as wide rivers and large lakes.

Activity Patterns

Prairie dogs are diurnal, usually appearing above ground at dawn during the warmer months and midmorning during the winter months. The heaviest above ground activity occurs between 7am and 11am and 5pm and 8 pm (Tileston and Lechleitner 1966, Biggins et al. 1993). *Cynomys ludovicianus* may spend as much as 95% of their time above ground during the daylight hours, and retreat into burrow for only 15-20 minutes to momentarily escape the heat (Hoogland 1995).

Black-tailed prairie dogs are not “obligate hibernators”; instead, they exhibit a state of facultative torpor due to food shortage (in captivity) during the winter months (Harlow and Menkens 1986) and/or weather (i.e., ambient temperature for free-ranging *C. ludovicianus*; Lehmer et al. 2001, 2003). Free-ranging females demonstrated facultative aestivation in summer months during periods of precipitation (Lehmer et al. 2003). Although *C. ludovicianus* demonstrate facultative torpor, they can be active throughout the year (Hoogland 1995). Facultative torpor is one area of prairie dog physiology and ecology that needs further study.

Reproduction and Survivorship

Breeding Behavior

Black-tailed prairie dogs exhibit a harem-polygynous mating system (Hoogland et al. 1987). Usually, one breeding male, two to three adult females, and one or two yearlings of each sex make up a territorial family group, or coterie, although as many as 26 prairie dogs may occupy the largest of coteries (Hoogland 1995). Fierce protection of coteries by males can lead to combat between males, but rarely leads to serious injury or death. Coterie size may vary from 0.05 to 1.1

ha and will contain a variable number of burrows depending on the number of animals, especially breeding females, on that coterie. Since prairie dog females usually stay on the natal coterie, this species avoids inbreeding by four mechanisms: 1) male biased natal dispersal, 2) older males disperse from coteries when daughters become sexually mature, 3) yearling females are unlikely to come into estrus when their father is on the colony, and 4) behavioral avoidance of mating with kin. These mechanisms are further explained in Hoogland (1995).

Breeding Phenology

The breeding season of black-tailed prairie dogs occurs between late January and early April (Clark and Stromberg 1987) and lasts for 2-3 weeks (Smith 1967). Timing of copulation is probably dependant on food availability and the severity of the preceding winter (Koford 1958, Smith 1967). Black-tailed prairie dogs are generally synchronized breeders (Hoogland 1981), breeding the same day in a coterie, and perhaps over 5 days throughout the colony (Hoogland 1995). Gestation is between 28 to 32 days (Smith 1967, Clark and Stromberg 1987). Altricial young are usually born in the early spring and emerge from burrows at about 6 weeks of age. Pups are fully grown in about 90 days (Clark and Stromberg 1987). Latitudinal differences in time of breeding are also evident; for example, *C. ludovicianus* in Texas and Oklahoma breed in January, in Colorado during February, and in Montana during March (Hoogland 1995, 1996).

Fecundity and Survivorship

Sexual maturity does not occur until 2 years of age (Smith 1967) differing from white tail prairie dogs which mature and breed at 1 year of age. Garrett et al. (1982) found that the age of first reproduction and pregnancy rate were both affected by the availability of food, and Knowles (1987) found that litter size is directly connected to precipitation level of the preceding year. Additionally, (Koford 1958) stated that breeding success is not necessarily depressed in small groups as it is in other social organisms like colonial nesting birds. An average litter size is 4 (Anthony and Foreman 1951) to 5 pups (Clark and Stromberg 1987) with the range occurring between 2 and 8 (Hoogland et al. 1987).

Survivorship of male prairie dogs can be 3 or 4 years old and females usually live to be 5 or 6 years old (see Figure 6; Hoogland et al. 1987). Natal survivorship is unknown, but infanticide has been documented and is considered the major cause of juvenile mortality within colonies (Hoogland 1995, 1996). Juvenile survivorship does not appear to be as sex-biased as adult survivorship with about 50% of each sex surviving their first year (Hoogland 1995).

Population Demographics

Metapopulation Dynamics

Although immigration and emigration to and from neighboring colonies is not important in maintaining genetic diversity (see below), maintaining corridors between distinct colonies is important for the long-term persistence of a metapopulation. A metapopulation can persist as long as rate of recolonization (i.e., after events such as plague eliminates a colony) exceeds rate of extinction. Increased isolation and disconnectivity of colonies will decrease successful dispersal between colonies, increase genetic diversity between colonies, and may decrease genetic diversity within isolated colonies through possible inbreeding and overall loss of alleles. Movement between existing or unoccupied colonies is affected by physical aspects of the surrounding landscape, such as tall grasses or urban and agricultural development. Maintaining corridors such as drainages, roads, or trails could facilitate recolonization of unoccupied colonies and continual dispersal among colonies (Roach et al. 2001).

Genetic Concerns

Dobson et al. (2004) demonstrated that the polygynous mating system (coteries within colonies) and female philopatry (see Dispersal below) of *C. ludovicianus* results in a strong genetic differentiation of coteries within a colony. This genetic substructure within a colony has a conserving influence on genetic diversity because different alleles predominate in different coteries, and decrease the loss of genetic diversity of the entire colony. In fact, the genetic diversity within a colony was influenced more from coteries within the colony than immigrants (males) from neighboring colonies. Translocation of females (essentially increasing the female dispersal rate) could actually increase the rate of inbreeding and loss of genetic variation by bringing related males and females into spatial proximity (Sugg et al. 1996, Dobson et al. 2004). This information should be considered when reintroducing or relocating *C. ludovicianus* to different colonies.

Food Habits

Cynomys ludovicianus is herbivorous, consuming the stems, leaves, seeds, and roots of various grasses, forbs, shrubs, and cacti. However, despite this breadth of food sources, black-tailed prairie dogs are not considered opportunists (Uresk 1984), apparently selecting for specific species of these growth forms. In fact, prairie dogs have been shown by Wydeven and Dahlgren (1982) and Fagerstone et al. (1981) to choose plants that are not abundant on the range colonized. Unlike other ground squirrels, and even other species of *Cynomys*, the black-tailed prairie dog does not store food in its burrow (Koford 1958) or hibernate during the winter.

The first known food habit study (Kelso 1939) found that western wheat grass (*Agropyron smithii*) and six-weeks fescue (*Festuca octoflora*) were most important followed by Russian thistle (*Salsola australus*), prickly pear cactus (*Opuntia* spp.) and saltbush (*Atriplex* spp.). Uresk (1984) found that only four plant species composed 65% of the diet of black-tails in South Dakota, of which grasses accounted for 87% of the diet and forbs composed 12%. Summers and Linder (1978), as well as Fagerstone et al. (1981) and Wydeven and Dahlgren (1982) also found that grasses are the most important component of prairie dog spring and summer diets, sometimes composing up to 90% of the food eaten.

Much controversy has arisen on the food habits of prairie dogs due to the potential for competition with domestic cattle (Uresk and Bjugstad 1983). However, steer weight gain on pastures with and without prairie dog grazing were not statistically significant (O'Melia et al. 1982, Uresk and Bjugstad 1983). Further, preferred plant species overlap between cattle and prairie dogs is not significant (Knowles 1986). Studies of the grazing relationship between bison (*Bison bison*) (Coppock et al. 1983b, Krueger 1986), pronghorn (Krueger 1986), and cattle (Knowles 1986) suggest that prairie dogs increase nutritional value of forage and change grazing habits by increasing shoot nitrogen and reducing standing dead biomass (Detling and Whicker 1987).

Seasonal change in diet is very common and is thought to occur in response to the decreased crude protein and increased fiber of mature plants (Fagerstone et al. 1981). Koford (1958) and Fagerstone et al. (1981) found that during winter, basal parts of buffalograss (*Buchloe dactyloides*), prickly pear cactus, fourwing saltbush (*A.canescens*), and rabbitbrush (*Chrysothamnus* spp.) were important. Shallow digging for roots may also be an important source of protein during winter (Tileston and Lechleitner 1966). During spring, the newly greening vegetation is preferred and the dominant species consumed are Russian thistle, scarlet globemallow (*S. coccinea*) and summercypress (*K. scoparia*). Shifts from C_3 to C_4 plants throughout the summer may occur in response to the subsequent greening of these species. During fall, the green bases of grasses such as buffalograss and blue grama (*Bouteloua gracilis*) are sought (Koford 1958, Fagerstone et al. 1981). Winter food items include mostly roots and prickly pear cactus (Summers and Linder 1978, Wydeven and Dahlgren 1982). Interestingly, prairie dogs have apparently developed the necessary physiology to cope with the oxalic acid occurring in prickly pear, in order to gain its moisture rich benefit in the winter diet (Fagerstone et al. 1981). It has been suggested that prairie dogs choose the most succulent form of vegetation available on a seasonal basis due to water stress (Fagerstone et al. 1981). Grass may compose as much as 85% of its wet weight as water (Hansson 1971), thus providing prairie dogs with the water needed for efficient assimilation (Becksted 1977).

Community Ecology

The potentially disproportionate influence of black-tailed prairie dogs in prairie ecosystems has led their being called keystone species, but this designation has been contentious (Stapp 1998; Miller et al. 2000). Prairie dogs (*Cynomys* spp.) are important members of grassland communities. They affect rangeland habitats by influencing plant species diversity and composition, creating habitat preferred by other wildlife species (May 2004). An estimated 170 vertebrate species have been alleged to rely on prairie dogs for some life needs (Clark et al. 1982; Reading and Matchett 1997; Lomolino and Smith 2003b). Well known obligates of prairie dog colonies include black-footed ferrets (*Mustela nigripes*) (Biggins et al. 1985, Reading 1993) and burrowing owls (*Athene cunicularia*) (Tyler 1968, Sharps and Uresk 1990), both of which depend on prairie dogs for burrow structures and/or food.

Prairie dogs are thought to affect many ecosystem processes (Detling and Whicker 1987) and habitat characteristics (Weltzin et al. 1997b), thereby having direct and indirect influences on the flora and fauna around them. For example, the black-tail's practice of "clipping" tall vegetation from burrow entrances to increase predator detection is similar to grazing and burning rangeland practices that encourage new plant growth, which is more nutritional and palatable to other wildlife species and domestic livestock (Knight 1994; May 2004). Removal of this species from prairie ecosystems could have effects on plant and animal species diversity and abundance over time. Lomolino and Smith (2003b) determined that *C. ludovicianus* towns harbored more rare and imperiled species (i.e., swift fox, black-footed ferrets, and burrowing owls), and therefore a decrease in prairie dogs could be detrimental to these species.

Conservation

Conservation Status

Federal Endangered Species Act

In 1998, two petitions were received by the U.S. Fish and Wildlife Service (USFWS) to list *C. ludovicianus* as threatened under the Endangered Species Act of 1973 (ESA). One petition was filed on July 30, 1998 by the National Wildlife Federation (NWF), and the second petition was received on August 26, 1998 from the Biodiversity Legal Foundation, the Predator Project, and Jon C. Sharps (see USFWS 2004b). These petitions listed several factors that could be major threats to the viability and conservation of *C. ludovicianus*, including habitat loss, habitat fragmentation, disease, unregulated shooting and poisoning, and the synergistic effects of these threats and others. The 90-day finding for the petitions was published in the Federal Register (FR) on March 25, 1999 (USFWS 1999) which stated that the petition action may be warranted. The 12-month finding by the USFWS on February 4, 2000 announced that listing *C. ludovicianus* was warranted but precluded (USFWS 2000), and therefore considered a candidate for listing.

Four of the five necessary conditions for listing were demonstrated (all were met except #2) (VanPutten and Miller 1999). These conditions were:

1. Present of threatened destruction, modification, or curtailment of habitat.
   This condition for listing was met by demonstrating the limiting of habitat, and reduction of populations, that has occurred largely due to agricultural interests.
2. Over-utilization for commercial, recreational, scientific, or educational purposes.
   This condition was not met. However, recreational shooting of prairie dogs may be reinvestigated in the future, depending on regulation of this activity by agencies.
3. Disease or predation
   This condition was met due to the high mortality (99.9%+) of prairie dogs faced with sylvatic plague. Unfortunate epizootics could easily eliminate the population.
4. Inadequacy of existing regulatory mechanisms
   This condition was met due to the classification of prairie dogs as pests in the states in which they occur. Adequate management actions to curtail recreational shooting and poisoning do not exist for many states.
5. Other natural or man-made factors affecting its continued existence.
   This condition was met due to reasons in #4.

Candidate listing required reassessments and resubmitted petitions to be listed annually in the FR (see USFWS 2001, USFWS 2002, USFWS 2004a). From these assessments and available scientific and commercial information it was determined that the petitioned action to list *C. ludovicianus* under the provisions of the Endangered Species Act (ESA) was not warranted on August 18, 2004. As a result, *C. ludovicianus* is no longer considered a candidate for listing (USFWS 2004b). The action to remove *C. ludovicianus* from the ESA candidate list was based on the following determinations: 1) destruction of habitat from agricultural conversion and other factors was no longer a threat, 2) modification of habitat due to the presence of plague was a moderate, imminent threat, 3) the present limitation of habitat due to chemical control was no longer a threat, 4) effects due to scientific or education purposes and commercial use of the species via the pet trade were not threats, 5) recreational shooting could be a low, imminent threat in some circumstances, 6) predation was not a threat, 7) disease was a moderate imminent threat, 8) the inadequacy of existing regulatory mechanisms was a moderate, imminent threat, and 9) chemical control and synergistic effects were moderate imminent threats (USFWS 2004b).

Bureau of Land Management

The State Offices of the Bureau of Land Management (BLM) in Montana, New Mexico, North Dakota, South Dakota, and Wyoming list *C. ludovicianus* on their sensitive species lists. According to the BLM Manual 6840, this designation is meant to provide protection of *C. ludovicianus* and the habitat on which they depend. Therefore the BLM is responsible for reviewing programs and activities on BLM land to determine their potential effect on *C. ludovicianus* (USDOI BLM Wyoming 2001; Keinath et al. 2003).

Forest Service

The range of *C. ludovicianus* encompasses portions of four forest service regions: the central part of the Northern Region (R1), the eastern half of the Rocky Mountain Region (R2), the eastern portion of the Southwestern Region (R3), and the western portion of the Southern Region (R8). Currently *C. ludovicianus* is listed as a sensitive species in Region 2 (http://www.fs.fed.us/r2/projects/scp/) and the subspecies, *C. l. arizonensis* is listed in Region 3 (New Mexico and Arizona; BISON 2004a).

State Wildlife Agencies

The Wyoming Game and Fish Department (WGFD) has developed a matrix of habitat and population variables to determine the conservation priority of all species in the state. Seven classes of Native Species Status (NSS) are recognized, with NSS1 representing critically imperiled species and NSS7 representing stable or increasing species. Classes 1, 2, 3, and 4 are considered to be high priorities for conservation attention. The WGFD assigns *C. ludovicianus* a special concern rank of NSS3. The NSS3 rank is based on WGFD estimates that *C. ludovicianus* populations in Wyoming are declining or restricted in numbers and/or distribution and habitat is restricted and/or vulnerable to human disturbance (Oakleaf et al. 2002; Keinath et al. 2003). Oklahoma also recognizes *C. ludovicianus* as a special management concern. See Table 2 for a complete list of state designations for *C. ludovicianus* across its range.

Heritage Ranks and WYNDD's Wyoming Significance Rank

The Natural Heritage Network assigns range-wide and state-level ranks to species based on established evaluation criteria (e.g., Keinath and Beauvais 2003, Keinath et al. 2003). *Cynomys ludovicianus* merits a global rank of G3 (averaged), which means that when the range-wide population is considered, it is deemed by Heritage scientists as rare or local throughout its range or found locally in a restricted range. This is based on evidence that the extent of occupied habitat and abundance has been reduced from its historic range (NatureServe 2004).

Twelve western states and provinces have assigned a State Rank to *C. ludovicianus*, none of which rank it as demonstrably secure (Figure 7). In general, state ranks are assigned based on the assessed risk of extinction within a state, where S1 species are deemed critically imperiled and S5 species are deemed demonstrably secure. These assessments are based on the biological information on population status, natural history, and threats at the state level. *Cynomys ludovicianus* is ranked as imperiled (S2) in New Mexico, Wyoming, and Saskatchewan; vulnerable (S3) in Kansas, Montana, Oklahoma and Texas; and apparently secure (S4) in Colorado, Nebraska and South Dakota. They are presumed extirpated (SX) in Arizona and their status is under review in North Dakota (SU) (NatureServe Explorer 2004; Keinath et al. 2003, Keinath and Beauvais 2003). The black tailed prairie dog was ranked as imperiled in Wyoming due to the following factors pertaining mainly to large towns (Keinath et al. 2003):

- Their range encompasses a moderate proportion (between 10% and 50%) of the state. Their historic range in Wyoming likely covered about 40% of Wyoming (Clark and Stromberg 1987). However, given fragmentation of habitat suggesting 0.01% of this historic range being occupied (Table 1), prairie dogs may actually cover less than 240,000 acres, or 0.004% of the state (e.g., Luce 2001). Wyoming likely contains about 17% of the historic black-tailed prairie dog range.
- They exhibit low range occupation (<20% of delineated range) and a patchy range-wide distribution. Historic distribution touches several states, including Montana, Wyoming, North Dakota, South Dakota, Nebraska, Kansas, Oklahoma, Texas, New Mexico, Arizona, and Colorado, but is quite patchy within this range.
- Their abundance within Wyoming is uncertain but probably declining (due to the intrinsic vulnerabilities and external threats noted below). At the turn of the century, black-tailed prairie dogs occupied more than 40 million acres, but estimates suggest less than 1% of that area is currently occupied (Merriam 1902 as cited in Van Putten 1999; Van Putten and Miller 1999). The area of occurrence is now very patchy (Mulhern and Knowles 1995). In Wyoming about 0.01% of historically occupied land contains currently active colonies (Luce 2001), which correlates to about 600,000 acres. However, estimates of active towns are al low as 130,000 acres (Mulhern and Knowles 1995).
- They have high intrinsic vulnerability due to habitat specificity and susceptibility to disease. Black-tailed prairie dogs are habitat specialists that occur mainly in flat, short and mixed-grass prairies with fine, non-sandy soils (e.g., Hall 1981;Miller et al. 1994; Clippinger 1989). Further, they are very susceptible to plague (*Yersinia pestis*), and Wyoming seems to be experiencing a statewide epizootic as of summer 2001 (personal communications with state land managers).
- They face high extrinsic threats, including active eradication programs, land conversion, and habitat fragmentation. Poisoning, shooting, land conversion can each be a substantial threat to black-tailed prairie dogs, but when combined they can devastate entire populations beyond the point of recovery (e.g. Luce 2001; Gilpin 1999).

The black-tailed prairie dog's Wyoming Contribution Rank is "high," because it is a native resident with a moderate proportion of its otherwise restricted continental range in Wyoming. Further, it has a restricted and patchy continental distribution and is arguably more secure in Wyoming relative to other states (Keinath et al. 2003, Keinath and Beauvais 2003).

Biological Conservation Issues

Abundance and Abundance Trends

No good estimate of *C. ludovicianus* abundance across its range is available, although it is estimated to be in the millions. Abundance of *C. ludovicianus* is generally expressed in terms of surface area (hectares/acres) occupied by their colonies (Miller and Cully 2001), as it is more cost-effective than surveying populations and calculating density. The USFWS believe that estimates of occupied habitat provide the best available and most reasonable means of gauging populations and status of the species across its range (USFWS 2004b). Ground-truthing exercises are currently being carried out in New Mexico, Oklahoma, Texas, and Wyoming; therefore, a better understanding of the accuracy obtained from using surface area occupied (obtained from aerial surveys) to estimate abundance will be gained (Luce 2003; USFWS 2004b). Using recent estimates of active *C. ludovicianus* acreage obtained from aerial and remote sensing surveys, estimates of *C. ludovicianus* abundance was calculated by multiplying each acre by the typical density of individuals per acre in colonies across its range (2 to 18 individuals per acre). From these calculations the most current estimated abundance of *C. ludovicianus* is between 3,684,000 and 33,156,000 (average 18,420,000; USFWS 2004b). At the beginning of the 19th century, *C. ludovicianus* numbered near five billion (see BISON 2004b). Thus the abundance of black-tailed prairie dogs has drastically decreased in the past century. It is estimated that *C. ludovicianus* has been reduced across its western range by about 98 – 99% of its former abundance (Wuerthner 1997).

In Wyoming, Mulhern and Knowles (1995) estimated that between 53,000 and 82,590 hectares were occupied by black-tailed prairie dogs. Estimates from 2003 indicate that *C. ludovicianus* occupy approximately 51,000 hectares, which conforms to the projected decline suggested by Wyoming Game and Fish Department as a result of plague-infested colonies (USFWS 2004b). In Wyoming, habitat loss or modification does not seem to be a large threat to *C. ludovicianus* populations, since very little habitat has been lost within the past 30 years (i.e., only 25,000 acres of rangeland converted to crops) and possible future land conversion is rather unlikely, since Wyoming's climate is not conducive to productive and economic crop growth (WBPDWG 2001). Please refer to Table 1 for a state-by-state account of occupied acreage and Table 2 for population trends throughout *C. ludovicianus* range.

Prior to 2003, most rangeland estimates of *C. ludovicianus* abundance were inconsistent and based on imprecise and cursory information, such as limited aerial surveys, review of available aerial photographs, and estimates from weed and pest control staff (Sidle et al. 2001; USFWS 2004b). These various methods provided incomplete and ad hoc data in order to determine abundance trends. For more valid estimates, methodologies across *C. ludovicianus* range need to be standardized. In addition, colonies need to be surveyed more regularly. Taking these actions will not only provide a more accurate estimate of abundance, but will also help document changes in populations as a result of plague, drought, and habitat alterations (see Inventory and Monitoring below).

Distribution and Connectivity Trends

At the turn of the 1900's black-tailed prairie dogs occupied more than 40 million nearly continuous hectares (Merriam 1902 as cited in Van Pelt 1999), and their range included portions of eleven States, Canada, and Mexico. Less than 1% of that area (< 324,000 ha) was occupied as of 1998 (VanPutten and Miller 1999). Despite the loss of habitat, *C. ludovicianus* are still widely distributed over their original range; although, they now occur in small, fragmented, isolated patches (Miller et al. 2000; USFWS 2004b). Arizona is the only state that the black-tailed prairie dog has been totally extirpated from its former range (Mulhern and Knowles 1995). Reduction in connectivity between colonies has probably had minor impacts on genetic diversity (see Roach et al. 2001, Dobson et al. 2004), but major impacts on recolonization success after serious population reductions (i.e., after plague or eradication efforts; see below).

Range contractions have been most evident in Arizona (now extirpated), western New Mexico, and western Texas through conversion of grasslands to desert shrub lands and in the eastern portion of *C. ludovicianus* range in Kansas, Nebraska, Okalahoma, South Dakota, and Texas through cropland development (USFWS 2004b). Most of the range reduction from agricultural development occurred in the early- to mid-1900s, and is a minimal threat today (see Extrinsic Threats).

The Interstate Black-tailed Prairie Dog Management Team plan states that Wyoming has a fraction (~ 0.01%) of the historical range currently occupied by active colonies (Luce 2003). In Wyoming, there is very little land under cultivation (< 5%), so the levels of land conversion observed in other parts of this species range have not impacted the species as severely. Competition with livestock ranching, and the control efforts that result (see Below), remains the main threat to further loss of species range. Landowner incentive programs may promote the use of some lands, currently used intensively for grazing, for prairie dog habitat.

Extrinsic Threats

The cause of *C. ludovicianus* population declines in the past century can be attributed to 1) intensive eradication programs, 2) agricultural conversion of rangelands, 3) sylvatic plague, 4) urbanization, and 5) recreational shooting. (Wuerthner 1997; Van Pelt 1999). The synergy of these threats may reduce populations drastically. The following section will address these issues. oisoning and shooting of prairie dogs by ranchers, and agricultural conversion of habitat are responsible for the majority of *C. ludovicianus* population decline (Miller et al. 1990, 1994)

Control Programs

Poisoning programs were initiated in the early 1900's when prairie dogs were first deemed an agricultural threat by Merriam (1902 as cited in Van Pelt 1999), with accusations that prairie dogs compete with domestic livestock for forage (Hoogland 1996). Both small-scale (i.e., trapping and drowning) and large-scale (i.e., poisoning and fumigation) eradication programs were used (Barko 1997). Since federal eradication programs were initiated in 1915, many federal land and wildlife management agencies, as well as state agencies, have been responsible for the extirpation of prairie dogs from millions of hectares (Anderson et al. 1986, Mulhern and Knowles 1995). In fact, it is thought that such poison eradication programs were responsible for the extirpation of *C. ludovicianus* in Arizona (see AGFD 1988). Despite modern evidence about grazing relationships (Coppock et al. 1983b, Uresk and Bjugstad 1983, Uresk 1984), and demonstration of the economic inefficacy of poisoning (Miller et al. 1996), this practice has continued into the 1990's with state and federal mandates. Though federal and state agencies have slowed poisoning in 1999 (WYGF 2001), private land owners are still permitted to exterminate prairie dogs from their lands. However, many states, including Wyoming, are developing incentive programs for private landowners to keep prairie dogs on their lands (WYGF 2001). Shooting also occurs for population control across the range of all 5 species in the U.S. (Mulhern and Knowles 1995). The USFWS (2004b) no longer consider control programs a threat to the persistence of *C. ludovicianus* populations across its range; chemical control programs and synergistic effects were considered a moderate imminent threat.

Recreational Shooting

Little is known about recreational shooting affects on *C. ludovicianus* populations; however, it is suggested that recreational shooting would only limit, not extirpate populations (Vosburgh and Irby 1998). Fox and Knowles (1995 in Mulhern and Knowles 1995) state that it would require one recreational day of shooting for every 6ha of prairie dogs to adversely affect populations. In addition, the USFWS (2004b) have found recreational shooting only a low, imminent threat, since it has been recognized that populations are capable of recovering from such adverse impacts. However, in some states, interest in recreational shooting has increased. Some States with large amounts of public land are experiencing increased shooting pressures on prairie dogs (USFWS 2004b). For example, in Wyoming, an increase in requests from the public as to where to shoot prairie dogs has been noted by Wyoming Game and Fish Department, Wyoming Department of Agriculture, and local Chambers of Commerce. This increased interest in prairie dog shooting, both locally and out-of-state has raised some concern that recreational shooting may become a significant contributor to *C. ludovicianus* population declines in Wyoming (WBTPDWG 2001). States concerned with increased recreational shooting are beginning to implement regulations to better monitor and control this activity (USFWS 2004b). Recently, Thunder Basin National Grassland has implemented a no shooting policy on 45,000 acres of prairie dog habitat in northeastern Wyoming (USDA 2004). This ban is one of the first of its kind on public lands. Other States, such as Arizona, Colorado, Montana, and South Dakota have also begun to restrict hunting on *C. ludovicianus* by limiting seasons and/or closing public lands. Still other States have begun to require hunting permits for public lands (Luce 2003). Shooting restrictions extended by some states on black-tails are a positive step; however, some researchers are concerned that it will cause a shift of shooting to the other species of *Cynomys* (VanPutten and Miller 1999).

Habitat Alterations

Reductions in *C. ludovicianus* habitat have occurred across its historical range, as a result of urban development and conversion of rangelands for agricultural purposes. Historically, it was conversion of short- and mixed-grass prairie for agriculture that was the major cause of populations decline, specifically in the eastern range of *C. ludovicianus* (Graul 1980, Dinsmore 1983). However, conversion of habitat from agricultural development is no longer deemed a threat to the persistence of *C. ludovicianus* (USFWS 2004b), since most of the arable land has already been converted (Mulhern and Knowles 1995). This reduced threat is in part a result of research by Sidle et al. (2001) that noted that vast areas of suitable habitat for colonization and expansion of this species still remain, as well as reports that estimate hundreds of millions of acres of potential habitat still remain intact (see USFWS 2004b and Table 1). Along the Front Range in Colorado, urbanization is considered one of the greatest threats to habitat loss (CBOS 1996; CDOW 2003). The USFWS (2004b) recognize that this may be a factor in habitat loss along the Front Range, but does not feel urbanization would present a substantial threat to *C. ludovicianus* across its entire range. In Wyoming, the population of Crook, Cambell, Johnson, Sheridan, and Laramie Counties has increased >10%, Weston, Converse, Platte, and Goshen Counties has increased by <10%, and the only county within *C. ludovicianus* range that has decreased, is Niobrara County (Miller 2001). The associated urban development with the population growth may become more of a threat to *C. ludovicianus* populations than has been present in the past.

Losses in extent and connectivity of native short- and mixed-grassland ecosystems of the Great Plains of North America have been drastic. Historically, *C. ludovicianus* range was continuous and covered >40 million hectares; however, over the past century, this habitat has been fragmented and reduced to less than 600,000ha (Miller and Cully 2001). Fragmentation of grasslands has occurred from such activities as agriculture, urban development (and its associated roads), and oil and gas development (Van Pelt 1999). As a result of this fragmented landscape, colonies have been isolated from one another, disrupting gene flow and successful distribution of dispersing males from their natal colony (Roach et al. 2001). Although habitat has been fragmented and some colonies isolated, it does not appear that this creates a great loss in genetic diversity (see Dobson et al. 2004). On the other hand, if populations are isolated from potential emigrating individuals, and the population within that colony is eliminated, it could become locally extinct. The USFWS (2004a) suggest that isolation of colonies may present a defense against the spread of plague, leaving some remnant populations unaffected and therefore do not deem habitat fragmentation an imminent threat to *C. ludovicianus* populations. In Wyoming, oil and gas development and population increase may become an issue, since suitable *C. ludovicianus* habitat is being developed (see Figure 8).

Although habitat loss appears to be a large threat to *C. ludovicianus* populations, it does appear that this species can adapt to various changes in their habitat. For example, Sidle et al. (2001) documented active *C. ludovicianus* colonies on small patches of grassland surrounded by agricultural development and near housing developments in Nebraska, and in the vicinity of roads and other developments in Wyoming.

Disease

Sylvatic plague (*Yersinia pestis*; known as Bubonic plague in humans) is an exotic bacterial disease that first entered the United States just before the turn of the century (Culley 1989). It was first discovered in the 1940’s in Texas (Cully et al. 1997). This disease has profound impacts on populations of prairie dogs (mortality ≥ 99%), which have little to no immunity. The plague can be especially devastating for isolated populations (see Wuerthner 1997). However, isolation of populations as a result of habitat fragmentation may be beneficial in preventing the spread of plague throughout entire metapopulations (see Habitat Alteration above). Plague not only has serious immediate effects, but long term population and demographic effects as well when coupled with shooting and poisoning. In fact the demographic changes imposed by such activities may place the species in an “extinction vortex” that the species may not recover from (Gilpin 1999). Populations west of the Dakotas commonly experience epizootics every 5-7 years (Culley, pers. comm.) and these outbreaks may hold the population level at about 40% of what it was before the epizootic (Knowles 1987).

Plague continues to be a threat to *C. ludovicianus* populations in Wyoming. Nearly all Wyoming populations of white and black-tailed prairie dogs have witnessed declines due to plague outbreaks since the 1930’s (WBTPDWG 2001). It is suspected that the plague is responsible for population declines in Wyoming (see Abundance Trends). Important locations of extensive black-tailed colonies, such as Thunder Basin National Grassland, have experienced losses of up to 70% of the total active acreage due to plague epizootics (T. Byer, personal communication).

The movement and maintenance of plague is not well understood (Anderson and Williams 1997) and needs further research. However, it has not yet expanded to cover the species national range. The occurrence of *Y. pestis* is generally west of the Dakotas; however, new reports indicate steady eastward movement in the southern part of the range, into Kansas (Cully et al. 2000). It is thought that the disjunctive and patchy distribution of *C. ludovicianus* populations throughout its range has prevented the devastating affects of plague on populations (WBTPDWG 2001).

Although the USFWS (2004b) considers plague the most important factor influencing black-tailed prairie dogs, they still only view plague as a moderate, imminent threat. They base their findings on the following information: 1) high exposure doses of plague bacilli may be necessary for disease contraction in some individuals, 2) limited immune response has been observed in some individuals, 3) a population dynamic may have developed in low-density isolated populations that contributes to the persistence of these populations, 4) the apparent ability of some sites to recover pre-plague levels after a plague epizootic, and 5) approximately one-third of the species' historic range has not been affected by plague.

Other

Predation of prairie dogs by coyotes (*Canis latrans*), badgers (*Taxidea taxus*), black footed ferrets (*Mustela nigripes*), bobcats (*Lynx rufus*), rattlesnakes (*Crotalis* spp), bullsnakes (*Piuophis melanoleucus*), golden eagles (*Aquila chrysaetos*), prairie falcons (*Falco mexicanus*), and accipiter and buteo hawks (*Accipiter* sp. and *Buteo* sp.) has occurred for as long as these species have inhabited the Great Plains. It is unlikely that these predators present a significant population threat to the species on their own (Hoogland 1981, 1996; WBTPDWG 2001). In addition, coloniality and antipredator calls offer a great predator detection system to minimize predation loss (Linner 2001). However, human predation in the form of recreational shooting may be an important adverse factor (see Recreational Shooting above), since recreational hunting can remove many individuals each day and change the demographic structure of metapopulations (Knowles 1987).

Invasive plant and animal species (other than plague, discussed below) do not appear to be a problem affecting prairie dog abundance or distribution.

Intrinsic Vulnerability

Habitat Specificity and Fidelity

Black-tailed prairie dogs occupy short- and mixed-grass prairie ecosystems, which can vary with respect to plant species composition, soil type, and topography (see Habitat). However, due to the colonial nature of *C. ludovicianus*, high fidelity for their habitat, once selected, is demonstrated. A loss of utilized habitat may cause populations to decrease.

Territoriality and Area Requirements

Within colonies, family groups (coteries) are extremely territorial defending their territory from other coteries (Hoogland 1995). Coterie's territories usually occupy about one-third of a hectare (Hoogland 1996); however, coteries occupying areas as large 1.01 hectares have been documented (Hoogland 1995). Since individuals of a coterie obtain 99% of their food and other resources within their territory, size and habitat quality is important (Hoogland 1995). Hof et al. (2004) estimated that one hectare could successfully maintain 18.4 individual prairie dogs. However, this number may be high for Wyoming. For example, when compared with other states within *C. ludovicianus* range, it appears that populations within Wyoming require larger tracts of land per colony, averaging 13 – 764 hectares per colony (see Clark et al. 1982). Fragmentation that reduces habitat availability may be detrimental to the populations.

Susceptibility to Disease

Although coloniality is thought to benefit communities of *C. ludovicianus* (i.e., predator detection), coloniality also promotes the spread of disease, which could significantly suppress local populations (Linner 2001). For example, sylvatic plague (*Yersinia pestis*), an exotic bacterial disease that first entered the United States just before the turn of the century (Culley 1989), has profound impacts on populations of *C. ludovicianus* (mortality ≥ 99%), which have no immunity. Plague can spread across whole *C. ludovicianus* complexes in just a few years (e.g., Anderson and Williams 1997, Cully and Williams 2001). Plague not only has serious immediate effects (mortality), but long term population and demographic effects, such as local extirpation of colonies, reduced colony size, increased variance in local population sizes, and increased distances between colonies. The latter can reduce the effectiveness of dispersal among colonies to recolonize after local extinction and increase the probability of extinction for entire complexes (Culley and Williams 2001). The effects of plague on populations are even more devastating when coupled with shooting and poisoning. In fact the demographic changes imposed by such activities may place the species in an "extinction vortex" that *C. ludovicianus* may not recover from (Gilpin 1999). Populations west of the Dakotas commonly experience epizootics every 5-7 years (Culley, pers. comm.) and these outbreaks may hold the population level at about 40% of what it was before the epizootic (Knowles 1987).

In Wyoming plague continues to be a threat to black-tail populations. The disease has not yet expanded to cover the species national range, but nearly all Wyoming populations of white and black-tailed prairie dogs have witnessed declines due to plague outbreaks. Important locations of extensive black tailed colonies, such as Thunder Basin National Grassland, have experienced losses of up to 70% of the total active acreage due to plague epizootics (T. Byer, personal communication). The movement and maintenance of plague is not well understood (Anderson and Williams 1997) and needs further research. The occurrence of *Y. pestis* is generally west of the Dakotas. However, new reports indicate steady eastward movement in the southern part of the range, into Kansas (Cully et al. 2000).

Dispersal Capability

Cynomys ludovicianus are capable of dispersing from natal colonies as far as 5km; however, *C. ludovicianus* will rarely disperse beyond the natal colony due to predatory risk without the warning "predator" calls of conspecifics (see Dispersal). In fact, it is estimated that survival rate decreases by 40% for each 5km dispersal distance (Hof et al. 2002). Roach et al. (2001) showed that prairie dogs within a 264km^2 area of the Central Plains Experimental Range and Pawnee National Grasslands in northern Colorado had a dispersal rate among established colonies of about 39%. It is largely unknown how often *C. ludovicianus* disperse to previously unoccupied sites, but is thought to be rare. Garret and Franklin (1988) demonstrated that dispersal rates increased as available food resources decreased. In highly fragmented colonies (i.e., urban and agricultural development), dispersal capability may be limited. The inability to disperse may create areas of high population density, increased competition for resources, and result in decreased habitat quality, which may lead to population decline and increased inbreeding (see Johnson and Collinge 2004). Other factors that could affect the dispersal of *C. ludovicianus* is the availability of high-visibility corridors or attractants such as chirping of other prairie dogs (Hof et al. 2002).

Reproductive Capacity

Hoogland (2001) demonstrated that *C. ludovicianus* have lower intrinsic rates of increase and are consequently more vulnerable to colony extinction than most other rodents. Five factors are responsible for this slow reproduction: 1) survivorship is <60% in the first year, 2) only one litter/year is produced, even under optimal conditions, 3) only 6% of males copulate as yearlings, 4) the probability of weaning a litter each year is only 43%, and 5) mean litter size at first juvenile emergence is usually 3.08. In addition, females may breed in their first year, but generally do not breed until their second year. On top of that, free-ranging species may only live three – to four years (Hoogland 1995). As a result, *C. ludovicianus* are slow to recover from population crashes such as a plague epizootic and must rely on recolonization from other colonies to recover or reestablish (see Metapopulation Dyamics). Cincotta et al. (1987) suggest that dispersing prairie dogs do not reproduce during their first year in a new colony. This may also play a factor in reproductive capacity. In spite of these facts, some researchers have suggested that *C. ludovicianus* are capable of rapid population increases subsequent to substantial reductions (see USFWS 2004b).

Protected Areas

In some areas of the species range, prairie dogs are protected from anthropogenically induced effects on national monuments, wildlife refuges and specially protected areas of federally managed lands. One such area is a shooting restricted zone in Thunder Basin National Grassland, Wyoming which provides approximately 20,000 acres. However, in contrast to the species range as a whole, the amount of protected area present is a very small percentage. The lack of large tracts of protected prairie dog range has caused some concern among managers due to the inter-colony dispersal that must occur to ensure long term survival of colony complexes that necessarily span large areas of land. As conservation plans are formulated and adopted by various management agencies, the amount of protected area is expected to increase. However, the extent of protections afforded and the extent of land thus impacted is currently uncertain.

Population Viability Analyses (PVAs)

For purposes of intensive management a suitable PVA has not been developed (Luce 2001). However, an interactive, web-based PVA model has been completed by Michael Gilpin at San Diego State University (SDSU) and contracted with the USFWS is available to view and use at http://gemini.msu.montana.edu/ ~mgilpin.prairie_dog.html. This PVA gives an excellent overview of many aspects of prairie dog management including an introduction to the metapopulation structure of black-tails. The interactive "applets" allow the user to manipulate varying conditions that effect population size and persistence such as plague and shooting.

Conservation Action

Existing Conservation Plans

The eleven states within the range of *C. ludovicianus* began a multi-state conservation effort in 1998 to promote conservation and avoid the federal listing of *C. ludovicianus*. The Black-Tailed Conservation Assessment and Strategy (CA&S) was developed in 1999. The purpose of the CA&S is to manage, maintain, and enhance habitat and populations of *C. ludovicianus* across its historic range and reduce the number of threats impacting their viability through the cooperation of private, tribal, federal, and state landowners. It provides actions, opportunities, and incentives for interested parties to become involved with conservation efforts of *C. ludovicianus*, as well as management suggestions such as eliminating mandatory control, regulating seasons or possession limits, maintaining and conserving required habitat and ecosystems, and establishing core populations on public lands to provide animals for dispersal to uninhabited areas or individuals for recolonization (Van Pelt 1999). In 2003 a Multi-State Conservation Plan (MSCP) was completed as an addendum to the CA&S to provide guidelines under which adaptive management plans will be developed by individual states and their respective working groups representing all stakeholders viewpoints (see Luce 2003). Currently ten of the eleven states in the range of *C. ludovicianus* have developed or drafted state prairie dog management plans: Interagency Management Plan for Black-Tailed Prairie Dogs in Arizona (Van Pelt et al. 2001), Conservation Plan for Grassland Species in Colorado (CDOW 2003), Kansas Black-Tailed Prairie Dog Management Plan (Kansas Department of Wildlife and Parks 2002), A Species Conservation Plan for the Black- and White-Tailed Prairie Dogs in Montana (Knowles 1999), New Mexico, North Dakota, Oklahoma (see Luce 2003), South Dakota Black-tailed Prairie Dog Management Plan (Cooper and Gabriel 2005), Texas Black-Tailed Prairie Dog Conservation and Management Plan (TBTPDWG 2004), Draft Wyoming Black-Tailed Prairie Dog Management Plan (Kruckenberg et al. 2001; WBPDWG 2001). Together, the CA&S, the MSCP, and the eleven state management plans hope to remove enough threats to *C. ludovicianus* in order to curtail needs for listing under the ESA while allowing for more flexible management practices. The following target objectives were created in the MSCP to help achieve this goal:

1. Maintain at least the currently occupied acreage of black-tailed prairie dogs in the U.S. (see Table 1).
2. Increase to at least 1,693,695 acres of occupied black-tailed prairie dog acreage in the U.S. by 2011.

3. Maintain at least the current black-tailed prairie dog occupied acreage in the two complexes greater than 5,000 acres that now occur on the adjacent to Conata Basin-Buffalo Gap National Grassland, South Dakota, and Thunder Basin National Grassland, Wyoming.
4. Develop and maintain a minimum of 9 additional complexes greater than 5,000 acres (with each state managing or contributing to at least one complex greater than 5,000 acres) by 2011.
5. Maintain at least 10% of total occupied acreage in colonies or complexes greater than 1000 acres by 2011.
6. Maintain distribution over at least 75% of the counties in the historic range or at least 75% of the historic geographic distribution.

The issue of recreational shooting is slowly being addressed over much of the range of black-tailed prairie dogs. Licenses that were previously un-necessary to shoot *C. ludovicianus* are now required in all states except Montana and Wyoming. However new management ideas have been presented by the Wyoming citizen's working group. These ideas include: temporary closing of shooting if population numbers decline to 15% above objective (200,000 acres) from current levels, develop management units/licensing protocols, and work with the public to develop management strategies (WYGF 2001). In Wyoming, shooting restrictions were enacted on focal populations in Thunder Basin National Grassland during the spring of 2001 to allow populations to expand in anticipation of black-footed ferret reintroduction. Future yearlong closures are proposed by the Wyoming Game and Fish Department (WYGF) for areas considered as important focal regions for conservation of the species (WYGF 2001). Wyoming G&F has begun to develop a memorandum of understanding (MOU) between agricultural, weed and pest, and wildlife commissions to limit poison distribution and to develop land owner incentives for keeping prairie dogs on their lands (WYGF 2001).

The National Forest Service (NFS) has also adopted management strategies to conserve *C. ludovicianus* on NFS lands (i.e., Thunder Basin National Grassland, Dakota Prairie Grasslands, and Nebraska National Forest Land) which are occupied (>70%) by *C. ludovicianus* populations (USDA 2004). These strategies include guidance and directions for the use of rodenticides, landownership adjustment, vegetation management, livestock grazing, prairie dog shooting/hunting, and other management options to either expand or limit growth of prairie dog populations and colonies on NFS lands (see USFWS 2004c).

Conservation Elements

Although *C. ludovicianus* has not been listed as threatened or endangered by the Endangered Species Act, the long-term decline in abundance and distribution across its historic range suggests that there is a need to undertake conservation actions to mitigate such a decline while viable populations still exist. This need is compounded by the fact that the *C. ludovicianus* provides habitat and a food source for a variety of wildlife species, including the endangered black-footed ferret (see Community Ecology). In Wyoming, conservation efforts should be attentive, since far less habitat has been lost in Wyoming than in most other states within the species' distribution (WBTPDWG 2001) and only 79% of suitable habitat is currently occupied by *C. ludovicianus* in Wyoming (see Table 1). Five main conservation elements should be addressed for *C. ludovicianus* conservation management in Wyoming. For more rangewide suggestions, please review Van Pelt (1999). Specific approaches that have been proposed to address these conservation elements are provided in the following section.

1. **Habitat Conservation**: Reduce conversion of land to uses not compatible with local persistence of *C. ludovicianus* and minimize impacts of semi-compatible uses, including livestock grazing and resource extraction.
2. **Disease Control**: The spread of disease (specifically sylvatic plague) among *C. ludovicianus* should be investigated and management should seek to minimize its impacts on prairie dog complexes.

3. **Shooting and Extermination Control**: Unless strictly controlled, recreational shooting and pest control efforts aimed at killing *C. ludovicianus* are not compatible with healthy populations.
4. **Inventory and Monitor Populations**: Current monitoring efforts are insufficient to generate reliable and comparable trend information and are therefore inadequate to track the future of *C. ludovicianus* populations. A thorough and consistent methodology must be applied in Wyoming and across its range, as discussed in the Inventory and Monitoring section below.
5. **Public Education**: In order to apply the above mentioned conservation elements to successful management programs in Wyoming, public attitudes toward prairie dogs need to change. Literature citing the importance of *C. ludovicianus* to rangeland habitat and its associated species need to be easily acquired and come in a variety of materials (i.e., brochures, videos, information boards, etc.).

Acting on Conservation Elements

There are many state citizens' working groups that have developed or are currently drafting conservation plans for *C. ludovicianus* and provide suggestions for management practices for *C. ludovicianus*. In addition, research published that focused specifically on *C. ludovicianus* has also provided management suggestions that may provide the best opportunity to conserve preferred habitat and viable populations of *C. ludovicianus*.

1. **Habitat Conservation**: It appears that conservation efforts to protect lands currently occupied (and adjacent) by *C. ludovicianus* is beneficial for maintaining or increasing abundance (see Table 2). Identifying tracts of lands occupied by *C. ludovicianus* (especially those >5,000 acres; see Van Pelt 1999) should be conducted through coordinated efforts of all federal agencies to maximize the conservation potential and preserve, if not increase, occupied habitat. In Wyoming, this objective is no less than 200,000 acres (WBTPDWG 2001). Maintaining large tracts of land will provide enough acreage and *C. ludovicianus* population to support reintroduced and recovering black-footed ferret populations, as well as other associated species (Luce 2003). Lomolino et al. (2003) suggest a mixed strategy for preserving habitat: maintain or develop widely

distributed large and small complexes (connected for dispersal purposes; Roach et al. 2001), and retain small and large isolated colonies throughout the range to help create barriers to prevent spread of the plague and potential eradication of metapopulations. Create buffers (~75 feet) around protected areas to provide area for expansion. In cases where adjacent land is not compatible with prairie dog colonies (i.e., hay or crop fields), create barriers beyond the buffers (i.e., tall grasses) to prevent establishment and/or foraging in these sites (CBOS 1996). Provide incentives for private landowners to voluntarily maintain prairie dog colonies on portions of their lands, since conserving *C. ludovicianus* habitat is not fully possible without the assistance of private landowners. In Wyoming, this is important, since private land constitutes a large percentage of total prairie dog habitat (WBTPDWG 2001). The multi-state conservation plan outlines a possible incentive program that could be pursued by individual states under such authorities as the Conservation Title of the Farm bill, Conservation Reserve Program, or Grasslands Reserve Program in Appendix E (Luce 2003). In addition, impacts that could adversely affect established or potential *C. ludovicianus* through urban, oil, and/or gas development should be minimized or eliminated. The following are suggestions to mitigate habitat alteration:

- Identify suitable habitat and current colonies before proposed oil and gas exploration and urban development sites are initiated.
- Determine local population densities, quality of habitat, spatial distribution of colonies and habitats (for connectivity and dispersal purposes), and how activities (i.e., drilling) may impact these factors.
- Locate roads outside areas of current, recent, or potential prairie dog habitats identified.
- Place restrictions on vehicle traffic (for mining operations) during the breeding season and dispersal (March through August) to help minimize stress and possible increased infanticide.

2. **Disease Control**: Currently there are no known vaccines to immunize *C. ludovicianus* against threat of the plague. However, steps can be taken to mitigate plague impacts. The multi-state conservation plan (Appendix D; Luce 2003) provides a plague protocol for all eleven states to initiate. It includes a plague monitoring protocol, procedures for visual evaluation of prairie dog colonies for plague, field procedures for collecting and handling

carcasses as diagnostic specimens, and procedures for swabbing rodent burrows. It is important to identify colonies in which the plague affected populations, and try to isolate these colonies from other complexes to stop the spread of the disease. In this case, colonies should be greater than 3km from their nearest neighbor colonies (Cully and Williams 2001). In addition, implementing the suggested mixed-strategy complex design (connected complexes with isolated colonies) will help reduce disease transmission, while maintaining some vital corridors to facilitate repopulation of eradicated populations (see Lomolino et al. 2003).

3. **Shooting and Extermination Control**: Unless strictly controlled, recreational shooting may not be compatible with healthy populations of prairie dogs, altering behavior and reproductive success, especially if this activity increases (Reeve, personal communication; Vosburgh and Irby 1998; USFWS 2004b). Further, unlike some threats (e.g., disease) it is well under the control of land managers. Optimally, shooting should be eliminated, particularly on otherwise impacted towns (i.e., large plague epidemics). During the past few years, several states have established better regulations (i.e., closures and season restrictions) that allow for management of recreation shooting; as well, they have changed the status of species from pest to a designation that recognizes the need for management. However, inn Kansas, North Dakota, and Wyoming, *C. ludovicianus* is still considered a pest and controlled as such (Luce 2003). The following are some restrictions that could help regulate recreational shooting of *C. ludovicianus* to assist in the conservation and protection of the species (Luce 2003):
    - Seasonal closures to all shooting during whelping and dependent young period (March 1 to June 30).
    - Require permits specific to designated areas and limit take.
    - Collect data on harvest (i.e., age and sex of animals harvested), hunter days per county, and hunter days/harvested animal through annual field checks and mail surveys, allowing State Wildlife Agencies to accurately quantify annual harvest.

    In Wyoming, *C. ludovicianus* is considered a pest and management is overseen by the Wyoming Weed and Pest Council, Board of Agriculture, and Wyoming Game and Fish Commission. Currently a memorandum of understanding is being drafted in which these agencies agree to limit the distribution of poisons and their participation in poisoning efforts when survey results indicate conservation plan objectives (i.e., acreage) is in jeopardy. Temporary restrictions on agency poisoning or cooperation with landowners using poison or other control methods should be implemented at local levels when necessary (i.e., poisoning compounding impacts by other threats to populations; WBTPDWG 2001).

4. **Inventory and Monitor Populations**: Conducting a baseline, state wide inventory of the number of acres contained within is crucial for long term population monitoring of this species. This information will allow management agencies to develop population targets, identify important population centers throughout the state, and give a measurable level of increase or decrease in population size under new management regimes. Sidle et al. (2001) present new estimates of prairie dog abundance in four states that are critically important to conservation of *C. ludovicianus*, and present a new aerial survey technique for abundance estimation that is replicable, includes estimates of precision, and does not require trespass permission from private landowners (Miller and Culley 2001; Sidle et al. 2001). It is important that methods range-wide are compatible with each other for comparison. The following strategies were outlined in the Wyoming conservation plan (WBTPDWG 2001):
    - Develop a cooperative effort to fund and conduct research and regularly scheduled inventories.
    - Continue to develop remote census techniques (i.e., Sidle et al. 2001).
    - Evaluate aerial transect techniques to identify the approach and sampling design best suited for Wyoming (see Appendix IX).
    - Conduct selected techniques in areas where ground surveys are being conducted (e.g., Thunder Basin National Grasslands) and evaluate accuracy and precision of techniques.
    - Coordinate with adjacent states to assure that results will be comparable.
        - Select a reliable method, and initiate inventories to document occupied habitat (initiated July 2002).
        - Conduct monitoring survey at three-year intervals from 2002.
5. **Public Education**: Lamb et al. (2001) conducted an eleven state survey within short-grass prairie systems regarding the public's attitude and knowledge of black-tailed prairie dogs.

Overall, the public did not highly regard *C. ludovicianus* and did not consider conservation of *C. ludovicianus* of great importance when compared with larger environmental issues, such as global warming. People will only value grasslands and prairie dogs to the degree that they understand them. Therefore, education of prairie dog may increase the desire to manage prairie dogs, especially since the anti-prairie dog attitude is still pervasive in federal, state, and public views (Knowles 1999; Lamb et al. 2001). Education and outreach materials should cover many topics including but not limited to prairie dog management, prairie dog ecology, plague, and effects of prairie dogs on rangelands and agricultural land. It is important that outreach materials and education programs are factual and represent interests of all stakeholder groups (TBTPDWG 2004). Examples of educational techniques could be: in-school presentation, nature hikes, slide presentations, brochures, and interpretative displays (CBOS 1996).

Habitat Preservation and Restoration

Habitat fragmentation and transformation of the Great Plains grasslands biome has been the most extensive of any in North America. This habitat alteration has impacted the continuity of large, historic habitat needed to establish extensive networks of prairie dog colonies and maintain inter-colony genetic diversity. Clearly, this is an important component of future conservation efforts. Programs that create, protect, and restore suitable habitat and connectivity offer some promise to provide habitat for successful prairie dog colonies/populations.

Roe and Roe (2003) offer guidelines to be used when selecting habitat for *C. ludovicianus* relocation efforts, which could be used for habitat restoration/preservation efforts (see Table 3). The guidelines present environmental parameters specific to soils, vegetation height, cover, and palatable species, slope, and optimal proximity to other established prairie dog colonies. In addition, Lomolino and Smith (2003b) and Lomolino et al. (2003) recommend conserving a network of native prairie reserves strategically located across the historic range of *C. ludovicianus*. They suggest that the network be comprised of “clusters” of large (presumably >10 ha, but size is not directly specified by the authors) towns, as well as large, isolated towns. The latter will be less likely to be infected or serve as a source for spread of the plague. Large towns will also be more likely support populations of *C. ludovicianus* and other associated vertebrates into the future (Lomolino and Smith 2001), buffering adverse effects from various extrinsic extinction forces (i.e., land conversion, expansion of roads, habitat reduction and fragmentation, and plague).

When restoring habitat for reintroduction of *C. ludovicianus*, whether to provide a food-base for black-footed ferrets, or to reestablish *C. ludovicianus* in their historic range, long-term planning is needed, as well as sufficient 1) area of land and habitat, 2) pre-introduction ecological studies and site preparation, 3) breeding individuals to make a reproducing population, 4) protection, and 5) monitoring and follow up studies (AGFD 2004).

Information Needs

Identifying specific information needs will help management agencies to formulate appropriate conservation strategies by targeting key areas needed for effective conservation of the species. The following list briefly notes some of the key information needed to develop sound *C. ludovicianus* conservation strategies.

1. **Inventory/Monitoring**: The development of long term monitoring and inventory of black-tailed prairie dog populations is needed. Without a way to reliably and quantitatively determine trends in abundance and distribution, managers have no way to assess the status of *C. ludovicianus* populations or the effect of management actions on these populations. Inventories should determine locations and sizes of colonies, land ownership, and presence of plague. Monitoring of known *C. ludovicianus* populations will help managers assess the affects of impacts, such as oil and gas projects, on population trends. Remote sensing and aerial and ground techniques need to be developed and standardized among agencies to ensure validity, smooth information flow, and communication (see Sidle et al. 2001).

2. **Disease**: Plague continues as one of the most detrimental threats to this species longevity and healthy population growth. Although some research has investigated the dynamics of plague in prairie dog colonies, there are still huge questions regarding its prevalence, cycle of occurrence, and distribution in the natural environment. Managers need to know how plague spreads between colonies and how it is maintained within colonies. Strategies allowing managers to predict and mitigate epizootics is very important given the catastrophic impact this disease has had on prairie dogs; for instance, field trials of vaccinations or parasite management strategies and/or real-time, large-scale, high-resolution mapping of epidemics. It is unknown if prairie dogs may one day develop immunity to the disease or if virulence will stay high.
3. **Shooting and Poisoning**: Recreational shooting effects have been studied preliminarily (Knowles 1987, K. Gordon, pers. comm.), but further research is needed to fully understand the impact of this activity on demographic structure and population dynamics. Depending on the outcome of ongoing studies, shooting may continue in some areas, but regulation and monitoring of this activity are keys to controlling its effects as evidenced by many years of hunting regulation for game species.
4. **Ecological Ramifications**: More research is needed on the long-term effects of *C. ludovicianus* on floral, faunal, and soil communities to determine if they are indeed a keystone species, and important for the persistence of a variety of species (see Community Ecology above).

Tables and Figures

Table 1: Baily Eco-Region habitat model distributions for each state (Native American tribes in Montana, South Dakota, and North Dakota set acreage objectives independent of states.)

State	Historic Habitat*	Current Habitat	Gross Habitat**	Suitable Habitat***	Minimum 10-Yr Objective
AZ	7,047,137	0	7,047	4,594	4,594
CO	27,352,880	631,102	273,529	255,773	255,773
KS	35,835,079	130,521	150,714	148,596	148,596
MT	60,442,757	90,000	297,286	240,367[1]	240,367[1]
NE	36,035,433	80,000	146,741	137,254	137,254
ND	11,045,269	20,500	110,453	100,551[2]	100,551[2]
NM	39,021,449	60,000	96,661	87,132[3]	87,132[3]
OK	21,606,120	22,000	70,868	68,657	68,657
SD	29,262,553	160,000	218,121	199,472[4]	199,472[4]
TX	78,592,452	167,625	310,945	293,129	293,129
WY	22,067,599	125,000	179,072	158,170[5]	158,170[5]
Total:	368,308,727	1,486,748	1,861,436	1,693,695	1,693,695

* Refers to total potential habitat encompassed within the range (Hall 1981), not occupied habitat

** Gross habitat = total acreage of primary range x 1% + total acres of peripheral range x .1% (Table 2 and Figure 3)

*** Suitable habitat = gross habitat minus habitat with >10% slope, or other unsuitability factors (Agricultural lands were included in suitable habitat if they fit the slope and suitability factors)

1 The acreage objective in the State of Montana's 2001 Management Plan is 90,000-104,000 acres for non-tribal lands. The state's acreage objective will be subject to modification in response to a financial incentives program for landowners if an incentives program is funded. Separate objectives will be set by individual Native American tribes.

2 The current acreage objective listed in the North Dakota Management Plan is 33,000 acres, including non-tribal and tribal lands. The state of North Dakota and the Standing Rock Indian Reservation will determine the target acreage for each jurisdiction. The state is willing to consider an objective of 100,551 acres on non-tribal lands if a financial incentives program for private landowners is funded. Tribal lands will have separate acreage objectives.

3 The New Mexico acreage objective is based on a percent increase per year, which would take approximately 10 years to achieve the current acreage objective. If future statewide survey efforts indicate a different acreage than the estimated minimum current acreage listed, the rate for achievement of the 10-year objective will be adjusted accordingly.

4 The acreage objective for South Dakota includes 169,551 acres of non-tribal lands and 29,921 acres of tribal lands (pending final approval of management plan).

5 Wyoming's draft management plan contains an objective to maintain the current acreage, or 200,000 acres, which ever is greater.

Table 2: Overview of *C. ludovicianus* status throughout its range.

Country	State/Province	State Status (May 2004)	Heritage Rank	BLM Species of Concern	Population Trend (USFWS 2004b)
United States					
	Montana	Nongame Wildlife; Pest	S3	yes	Decreasing[3] Increasing/Stable[4,5]
	North Dakota	Nongame Wildlife	SU	yes	Stable?/Decreasing?
	South Dakota	Game Wildlife; Varmint	S4	yes	Increasing/Stable[4]
	Wyoming	Species of Special Concern	S2	yes	Decreasing[3] Stable[4]
	Nebraska	Nongame Wildlife	S4	nr	Absent[6] Increasing[4]
	Kansas	Wildlife	S3	nr	Absent[6] Increasing[4]
	Colorado	Small Game Species	S4	nr	Decreasing[1,3] Increasing[4,5]
	New Mexico	No Legal Listing	S2	no	Absent[6] Stable?
	Arizona	Extirpated; Nongame mammals	SX	no	Extirpated[1,2]
	Oklahoma	Species of Special Concern	S3	nr	Absent[6] Stable?
	Texas	Nongame Wildlife	S3	nr	?
Canada					
	Saskatchewan	Special Concern	S2	n/a	Stable[4]
Mexico					
	Amenazada	Threatened	n/a	n/a	Absent[1,2,6] Stable[4]

Heritage Rank: SU = unknown, SX = extirpated, S2 = imperiled, S3 = vulnerable, S4 = apparently secure

BLM Species of Concern:
yes = the State's BLM office recognizes *C. ludovicianus* as a Species of Concern
no = the State's BLM office does not recognize *C. ludovicianus* as a Species of Concern
nr = not reported

Population Trend: 1 = habitat conversion, 2 = control efforts, 3 = plague, 4 = habitat preservation, 5 = recovered, 6 = absent from historic range, ? = not enough information

Table 3: Guidelines for *C. ludovicianus* habitat restoration and preservation. Adapted from Roe and Roe (2003).

Parameters		**Description**
Vegetation	species	western wheatgrass (*Pascopyrum smithii*), blue grama (*Bouteloua gracilis*), buffalograss (*Buchloe dactyloides*), sand dropseed (*Sporobolus cryptandrus*), cheatgrass (*Broums tectorum*), sixweeks fescue (*Vulpia octoflora*), ring myhly (*Muhlenbergia torreyi*), sedges (*Carex* spp.), scarlet globemallow (*Sphaeralcea coccinea*), and plains prickly pear (*Opuntia polyacantha*).
	cover	<40% bare ground; shortgrass prairie grasslands 58-70%; …
	height	<30cm
Soil	depth	≥2.0m
	type	loamy with little to no gravel; low in clay (<30%); meduim in sand (~50%); medium to high in silt (>70%) with good drainage.
Slope		< 20%; preferably ≤10%
Proximity to established colonies		≥46m and up to 185-277m

Figure 2: Drawing of skull morphology of *C. ludovicianus*, adapted from Hoogland (1981).

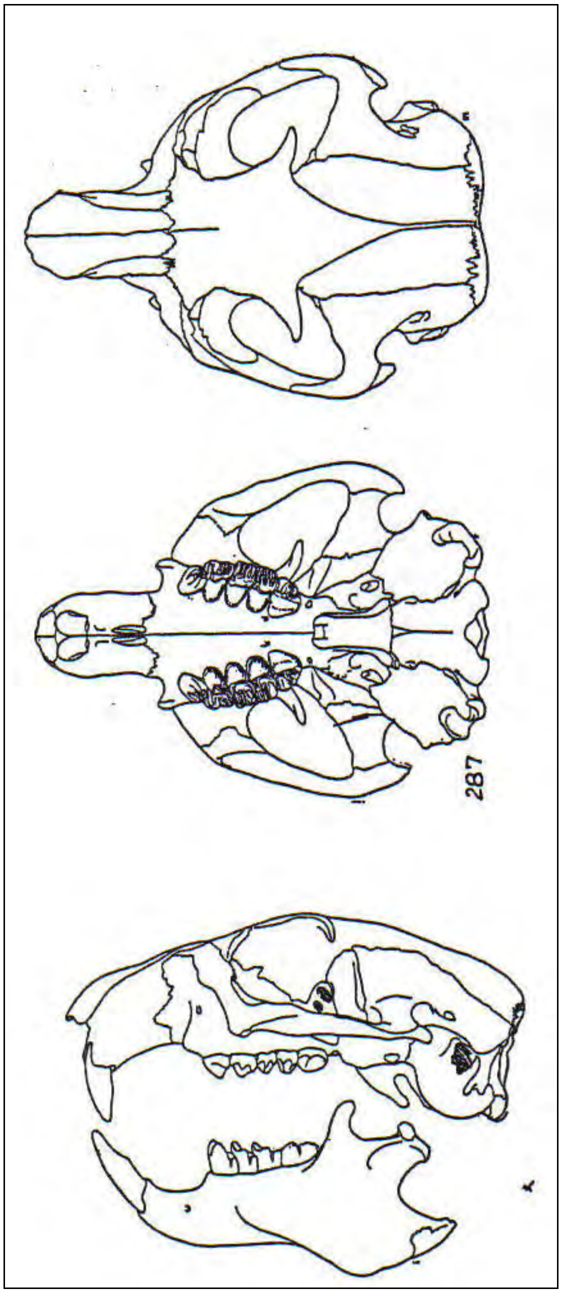

Figure 3: North American range of all prairie dog species from Hall (1981).

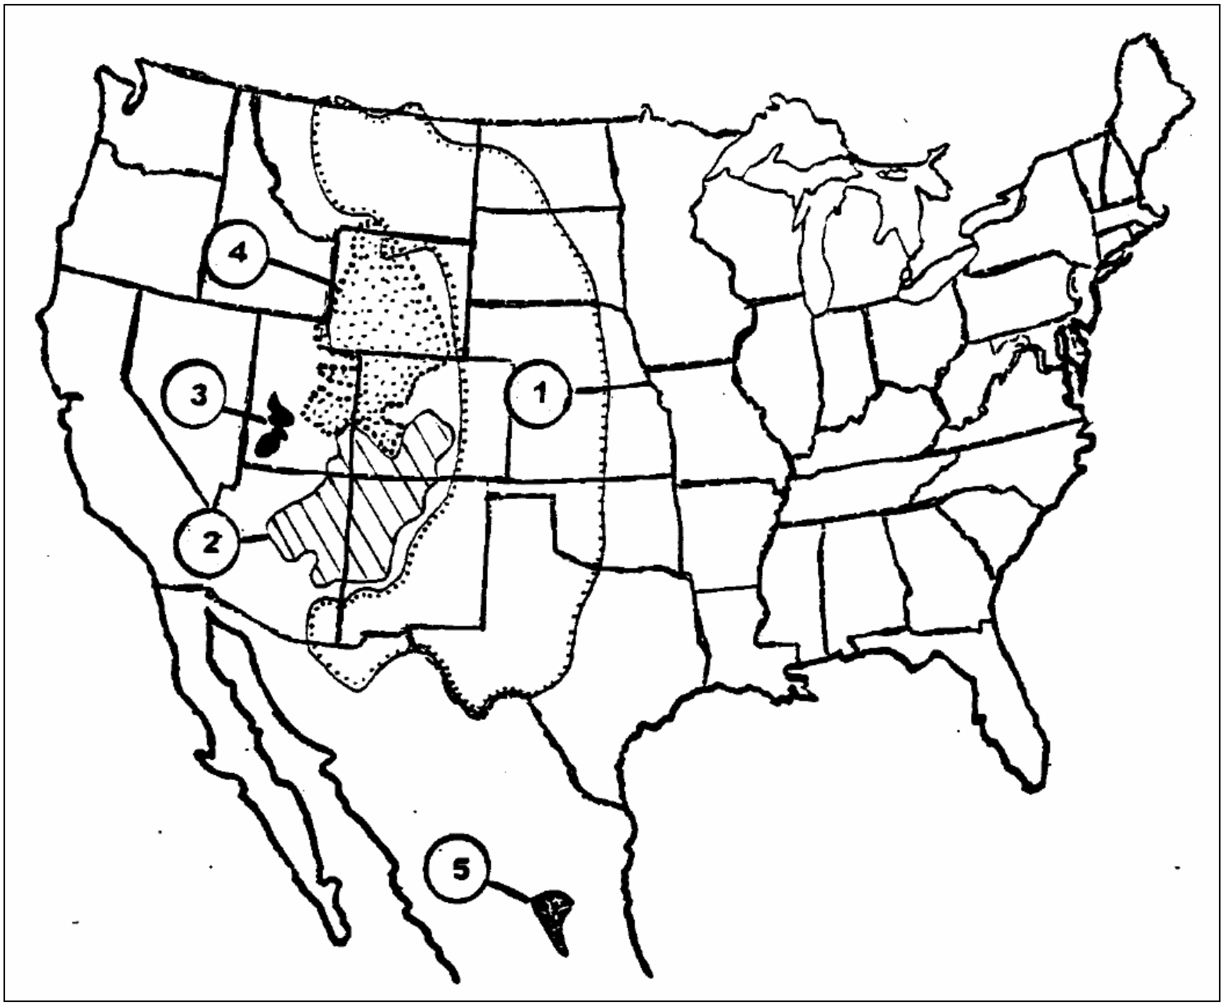

1. Black-tailed prairie dog
2. Gunnison's prairie dog
3. Utah prairie dog
4. White-tailed prairie dog
5. Mexican prairie dog

Figure 4: Possible distribution of *C. ludovicianus* based on mixed-grass and short-grass prairie distribution in eastern Wyoming (map acquired from WYGISC website: www.wygisc.uwyo.edu).

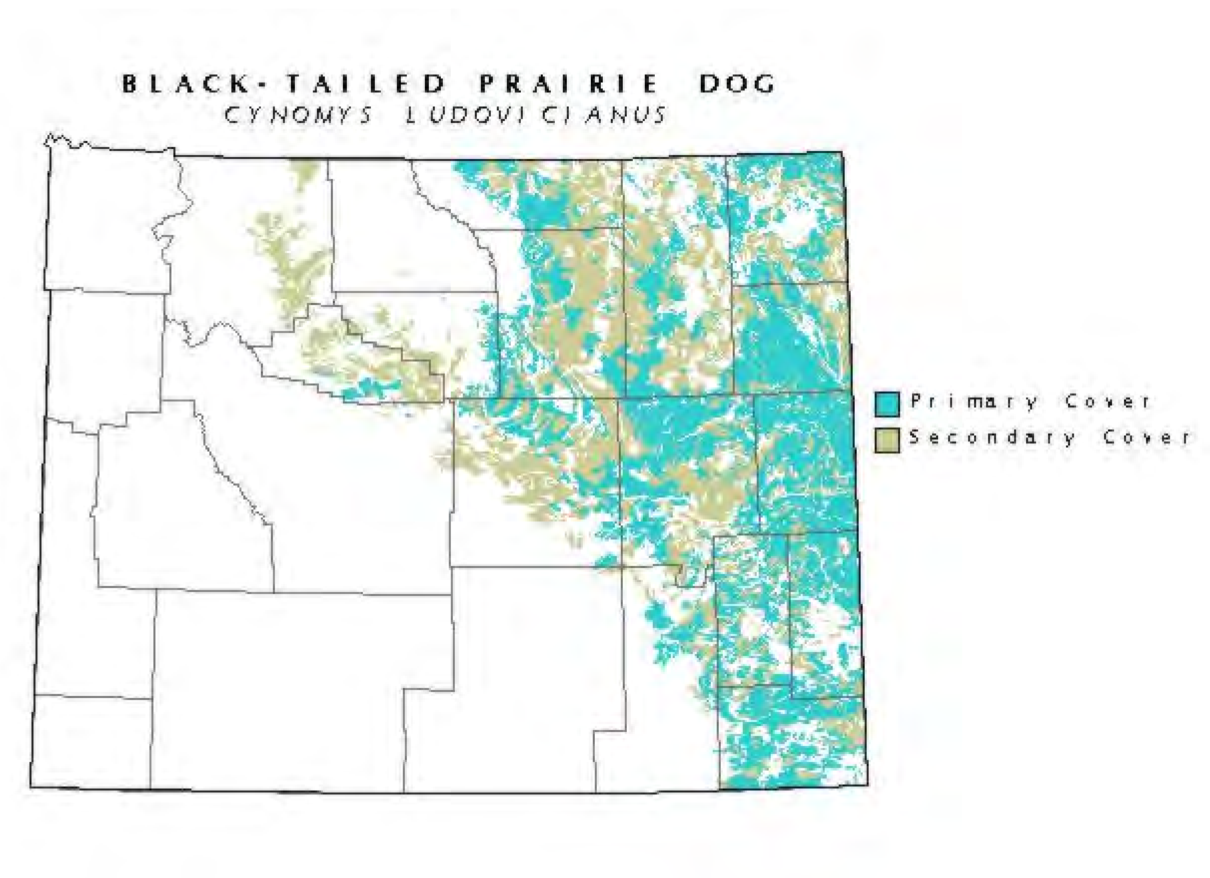

Figure 5: Rangewide distribution of the black-tailed prairie dog. Outline is the historic distribution from Hall (1981) and the shaded portion of the range map is from State surveys. This map does not include current distribution of populations in Canada and Mexico (acquired from Luce 2003).

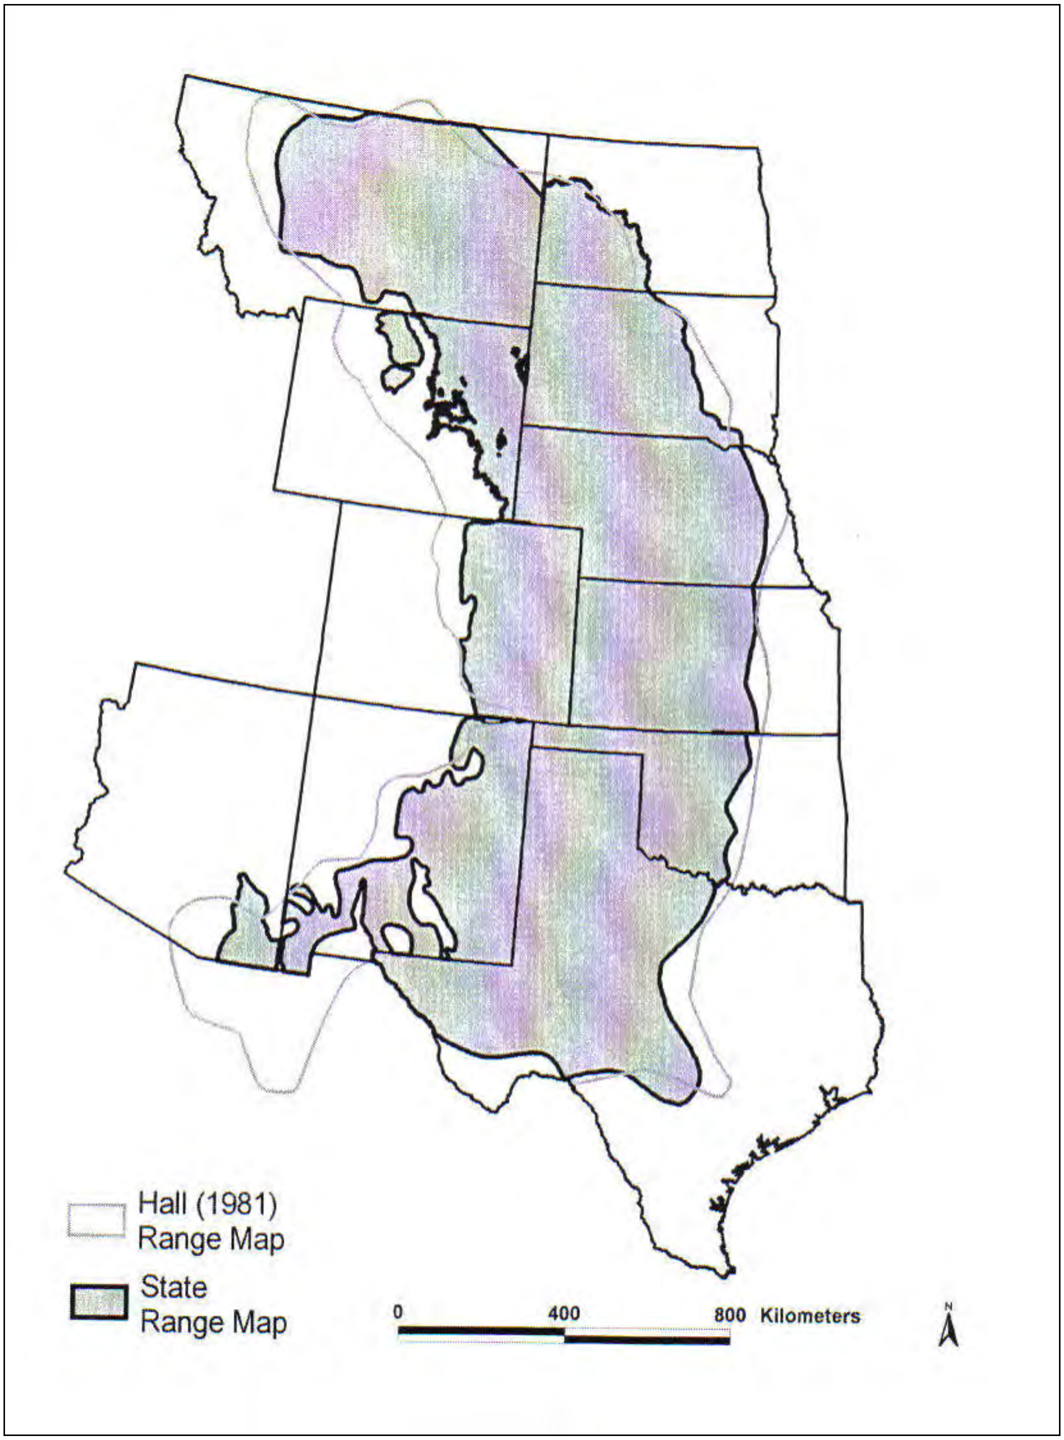

Figure 6. Loop diagram depicting a) life cycle and b) related matrix model elasticities for female black-tailed prairie dogs (*Cynomys ludovicianus*) (courtesy J. Pauli, University of Wyoming). Pi denotes the probability of surviving to the next age class and Fi denotes the fertility of that age class. eij denotes the elasticity from age class j to age class i. Although female black-tailed prairie dogs can reach an age of 9, age classes >6 were excluded in elasticity analyses because older age classes fail to reproduce. The basic loop diagram was constructed from J. Hoogland's 14 year study (1975-1988) of black-tailed prairie dogs in Wind Cave National Park (Hoogland 1995).

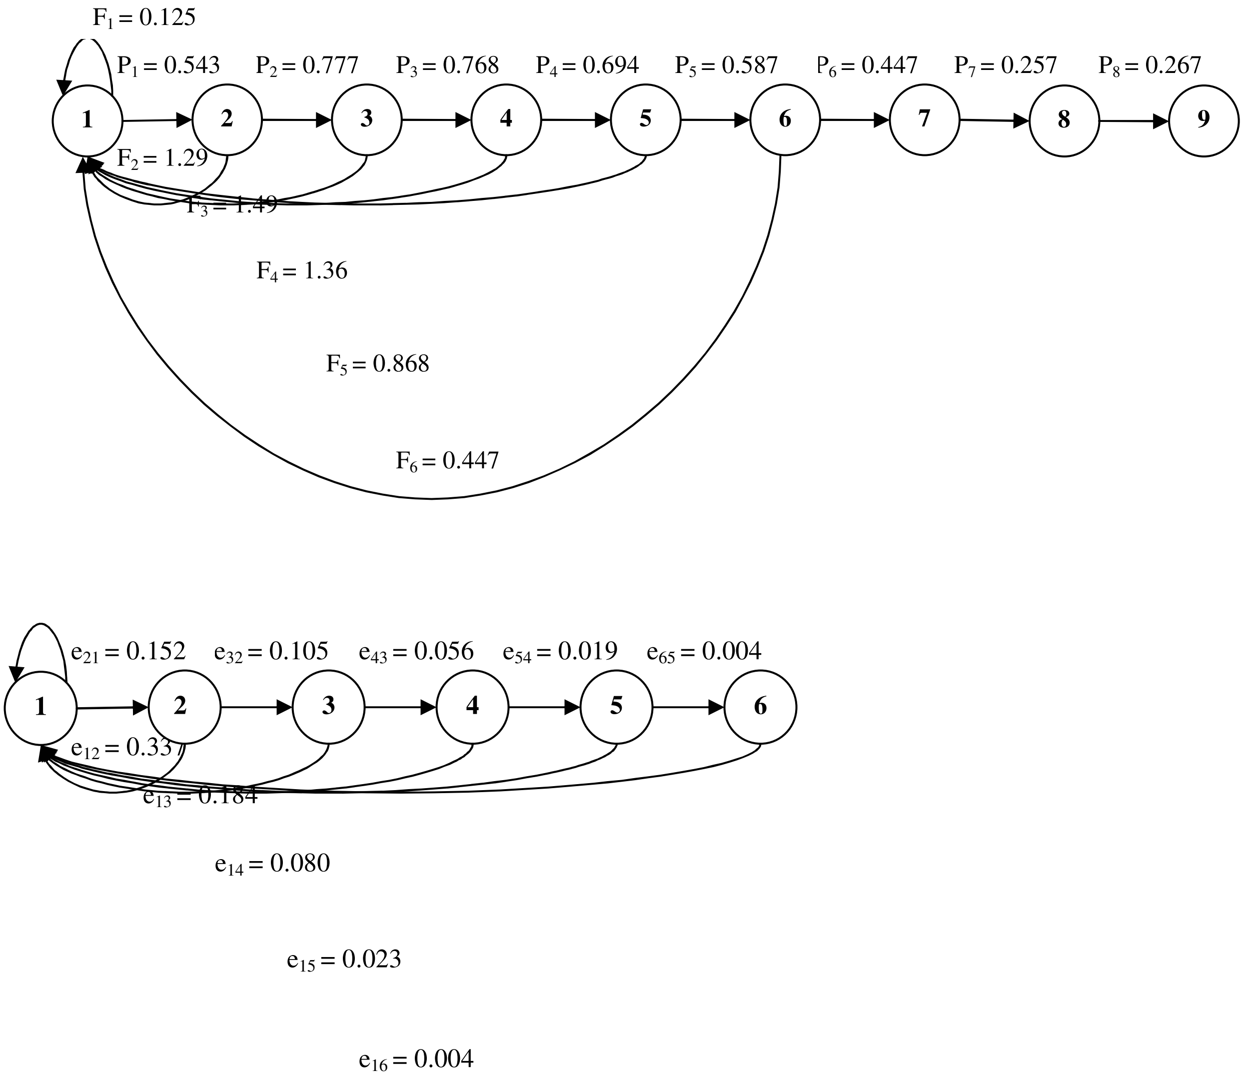

Figure 7: Map of Natural Heritage Ranks for the black-tailed prairie dog (NatureServe 2004).

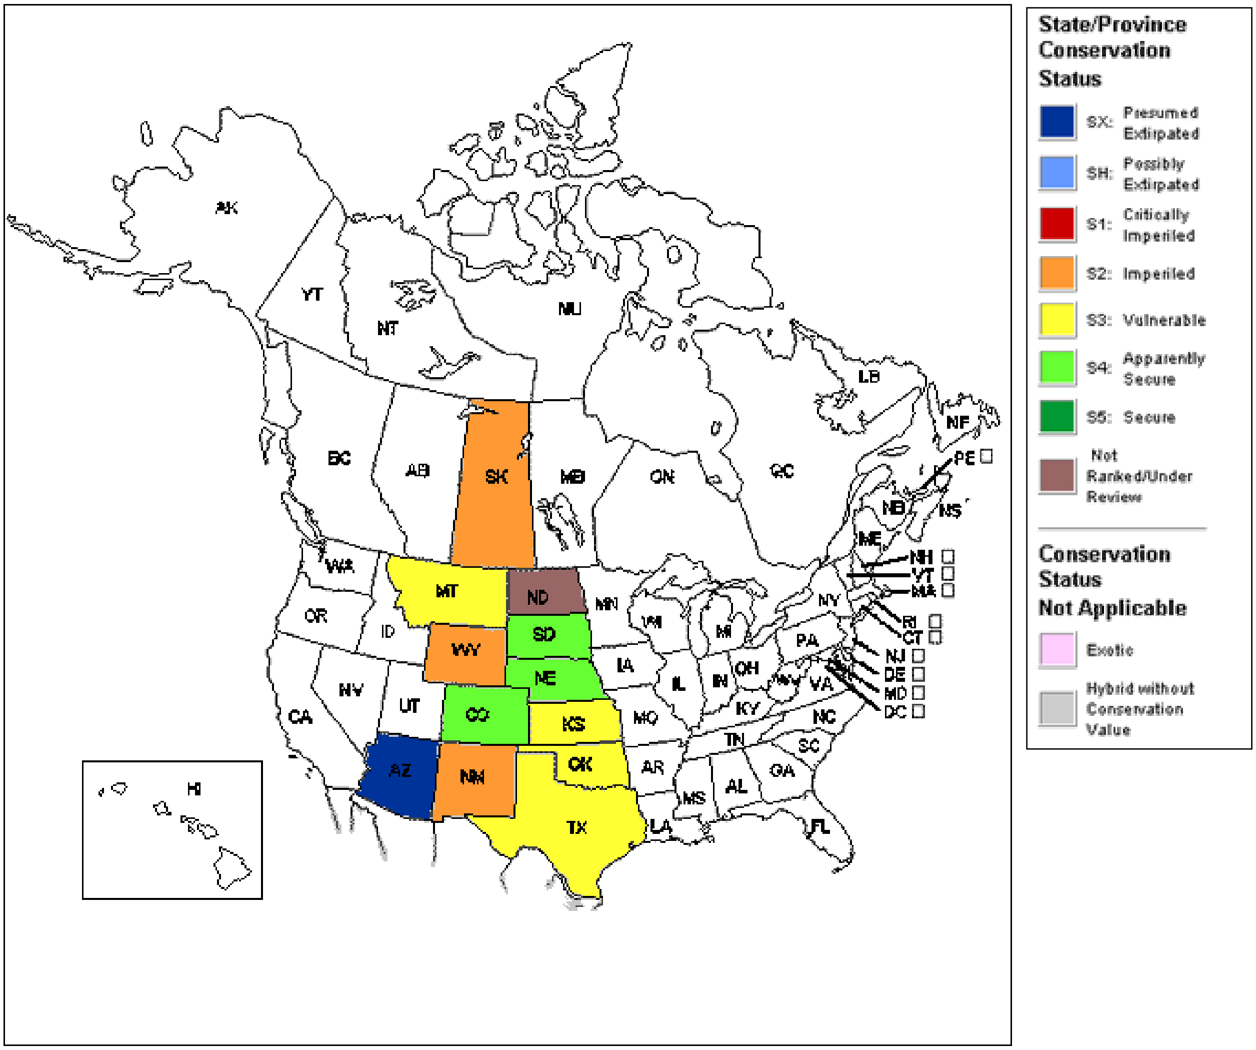

Figure 8: Existing oil and gas developments in Wyoming (Knick et al. 2003, p. 619). Note the amount of development in the northeast section of Wyoming, where the largest populations (acreage) of C. ludovicianus have been reported.

ALTERATION OF BISON AND BLACK-TAILED PRAIRIE DOG GRAZING INTERACTION BY PRESCRIBED BURNING

D. LAYNE COPPOCK,[1] Natural Resource Ecology Laboratory, Colorado State University, Fort Collins, CO 80523
JAMES K. DETLING, Natural Resource Ecology Laboratory and Department of Range Science, Colorado State University, Fort Collins, CO 80523

Abstract: Bison (*Bison bison*) use of a black-tailed prairie dog (*Cynomys ludovicianus*) colony was compared before and after a prescribed burn on adjacent, uncolonized grassland at Wind Cave National Park (WCNP), South Dakota, 1979–80. On a daily basis cow-calf herds increased their use of the burned grassland 12× and decreased their use of the colony by 30–63% following the burn. Prescribed burns could be effective in mitigating bison impacts on colonies.

J. WILDL. MANAGE. 50(3):452–455

Bison are attracted to grassland sites altered by prairie dogs (Koford 1958, McHugh 1958, Shult 1972). Coppock et al. (1983*a*,*b*) demonstrated that bison feed selectively on moderately grazed, grass-dominated areas near the perimeters of prairie dog colonies. These areas have more readily digestible perennial grasses with higher nitrogen concentrations and greater accessibility of green tissues than vegetation from uncolonized areas (Coppock et al. 1983*a*). Prairie dog colonies may receive a disproportionate amount of bison use in relation to their area. For example, a colony that comprised 39% of Pringle Valley in WCNP, South Dakota, received 90% of all bison feeding activity in that valley during the summer of 1979 (Coppock et al. 1983*b*).

Prolonged grazing pressure on colonies results in marked changes in plant composition (Coppock et al. 1983*a*), and because bison exacerbate impacts of prairie dogs (Coppock et al. 1983*b*), ways are needed to attract bison elsewhere. Because ungulates are attracted to burns (Vogl and Beck 1970, Davis 1977), we hypothesized that bison use of burned areas would increase with an accompanying reduction of their preferential use of prairie dog colonies. The objectives of this study were to contrast feeding-site selection by bison before and after a prescribed burn of grassland adjacent to a prairie dog colony and to evaluate the implications for management at WCNP.

We thank R. W. Klukas and the WCNP staff for facilitating our research. We gratefully appreciate the logistical assistance of Drs. J. H. Bock and C. E. Bock (Dep. Environ. Popul., and Organ. Biol., Univ. Colorado, Boulder), and the help of T. B. Fraas, B. D. Gueck, and P. I. Schiefer during data collection. This work was supported by Natl. Sci. Found. grants DEB-7682821 and BSR-8406660.

METHODS

Studies were conducted in Pringle Valley (120 ha) in the northwest corner of WCNP. The uncolonized grassland (84 ha) was dominated by little bluestem (*Andropogon scoparius*), big bluestem (*A. gerardi*), Kentucky bluegrass (*Poa pratensis*), and western wheatgrass (*Agropyron smithii*). The prairie dog colony (36 ha) contained plant associations that ranged from closely cropped grass-dominated areas (27 ha) in the outer margins to a forb (sweetclover [*Melilotus* spp.], ragweed [*Ambrosia*], and aster [*Aster* spp.]) and dwarf-shrub (fringed sagebrush [*Artemisia frigida*]) community (9 ha) in the center.

A 9-ha prescribed burn was conducted on

---

[a] Colony denotes black-tailed prairie dog colony.

[b] Significance denotes high daily repeatability of pattern as evaluated using Friedman's test (Steel and Torrie 1980:546).

uncolonized grassland adjacent to the northeast edge of the colony in October 1979. The burn resulted in extensive reductions of standing-dead grass and litter (Bock and Bock 1983, 1984).

Observers quantified bison site selection and behavior (feeding or resting) from June to August in 1979 (preburn) and 1980 (postburn) from a fire tower. Bison location and site-specific activity during the daylight hours were recorded at 30-minute intervals (Coppock et al. 1983*b*). Observations were made daily in 1980 but only 5 days/week in 1979. Valley sites included: (1) the grass-dominated (young) portion of the colony (28% of the area as visible from the tower), (2) the old forb and dwarf-shrub area of the colony (11%), (3) the uncolonized grassland before and after burning (11%), and (4) unburned, uncolonized grassland (50%). Bison feeding-site selectivity was calculated daily for cow-calf herds (typically >100 animals) and bull groups (typically ≤5 animals). Cows with young were transient visitors to the valley, whereas bulls were present throughout the summer. Feeding-site selectivity was calculated as the percent observed : percent expected feeding time for a given site. Expected percentage of feeding time was assumed to be equal to the percent availability of sites if feeding was random. Random use would yield an index of 1.0 for all sites, whereas selection or avoidance of areas would yield values greater or less than 1.0, respectively.

Each day of observation was considered an independent sample of bison use of the valley. Friedman's test (Steel and Torrie 1980:546) was used to evaluate the daily repeatability of feeding pattern for cow-calf herds and bull groups in each year by ranking the site-selection indices (Coppock et al. 1983*b*). Because this index was distributed normally, *t*-tests were used to compare mean selectivity values for each site between bison herd types in each year and between years for each herd type.

RESULTS

Approximately 8,300 animal hours of feeding time were recorded during 76 days across both years. About 70% of the observations occurred in 1980 (Table 1). Although we did not keep a daily census for bulls in 1979, daily records indicate cow-calf herds increased their use of the valley in 1980 (21 total visits, of which 19 were sampled) compared to 1979 (16 total visits, of which 8 were sampled).

Before the burn in 1979, cow-calf herds grazed nearly 3× as much as expected on the young colony site, randomly used the old colony, and used the uncolonized areas less than expected in a highly repeatable daily pattern (Table 1). Site selectivity by bull groups was similar to this, but bulls were more variable on a daily basis. Following the burn in 1980, cow-calf herds exhibited a 12× increase ($P < 0.01$) in selection for the burned site, and significantly reduced ($P < 0.05$) their selection for the young and old colony for feeding compared

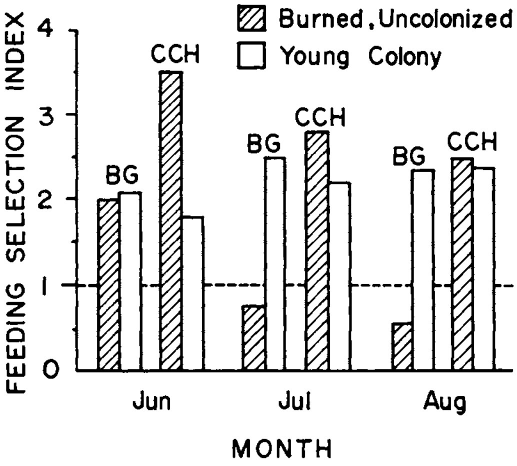

Fig. 1. Monthly feeding selection of a burned, uncolonized site and a young, grass-dominated black-tailed prairie dog colony site by bison in Pringle Valley, Wind Cave National Park, South Dakota, 1980. The selection index was calculated as percent total feeding use divided by percent site availability; values >1.0, 1.0, and <1.0 indicate selection, random use, and avoidance, respectively. BG = bull groups and CCH = cow-calf herds.

with the previous year (Table 1). In contrast, the burn had little effect on use of the valley by bull groups. The burn site and young colony were selected to a similar degree ($P > 0.05$) by bulls in both years, yet significant ($P < 0.01$) changes in selection of old colony and other off-colony areas occurred between years (Table 1).

Monthly patterns of feeding-site selection also varied between cow-calf herds and bull groups in 1980. The most pronounced variation occurred for selection of the burned site, as use of the young colony was consistently high by all bison throughout the summer (Fig. 1). Although all bison groups selected the burned site more in June, bulls used it less than expected in July and August. In contrast, cow-calf herds exhibited a high selection for the burned site regardless of month (Fig. 1).

DISCUSSION

Our results indicated that cow-calf herds did increase their use of the burned site the 2nd year and consequently decreased their use of the prairie dog colony for feeding. Bison may have been attracted to the burn because of chemical and structural changes in the vegetation that produced a higher diet quality for animals grazing there. Burning has been demonstrated to enhance forage nutrient content (Campbell et al. 1954, Bendell 1974, Hobbs and Spowart 1984), but effects may be minor and short-lived unless followed by frequent regrazing. Hobbs and Spowart (1984) suggested that increased accessibility of green forage was the major factor in the higher diet quality of montane ungulates using burned sites. This is a particularly good hypothesis for bison, which are relatively unselective feeders and may otherwise ingest large proportions of standing-dead herbage along with live tissue from stands of mature grasses.

Bulls were less attracted to the burned site than cow-calf herds. This might be explained by large differences in group size, which may have influenced the perception of, or need to exploit, so large a feeding patch. Both cow-calf herd and bull groups tended to use the burned site more in June before extensive greenup of Pringle Valley, which was dominated by warm season grasses. However, only cow-calf herds consistently regrazed the burned site during the rest of the summer. It is possible that bulls could better satisfy their foraging needs from a greater array of smaller patches. The regular use of the colony (also a large patch) by bulls appears contradictory to this argument, but this area, unlike the burned site, had the additional attraction of wallows (Coppock et al. 1983*b*). Dusting activities by bulls usually intensify by mid-summer because they are associated with antagonistic activities among males during the rut (Petersburg 1973). Wallowing, as well as better foraging conditions, may have contributed to the attraction of the colony for bulls. Such activity complicates comparisons of site selection based on forage characteristics alone.

Because cow-calf herds comprise nearly 70% of the bison in WCNP, the observation that burning can lure them from prairie dog colonies is important for grazing and habitat management. Heavy grazing by bison likely contributes to long-term changes in plant composition and productivity on colonies and may hinder vegetative recovery in sites where prairie dog populations have been reduced to meet management objectives. This study indicates that use of the colony by cow-calf herds for grazing was reduced about 35%/visit in postburn 1980 compared with preburn 1979. However, this daily reduction may have been largely negated by the increased use of this valley during the 2nd year, and the increased use may have been causally related to the prescribed burn. Therefore, we recommend that burning be located a considerable distance from colonies to minimize bison impacts. Control burning has been suggested as a useful tactic in manipulating free-ranging herds (Edwards 1984), and it may be possible to include this perspective within the ongoing management program at WCNP. Strategic placement of burns also should incorporate knowledge of bison travel routes and distributions of mineral licks and water.

RE: Follow-up to meeting on Thunder Basin National Grassland

Dear Mr. Ferebee and Ms. Buchanan,

We are writing in follow-up to our meeting with Ms. Buchanan on current and future collaborative efforts for sustainable management of Thunder Basin National Grassland's (TBNG) natural resources. We urge the Forest Service to move forward with implementation of the current TBNG Land and Resource Management Plan (2001), including the prairie dog management strategy as outlined in plan amendment #3 (2009). As long-term vested partners, we strongly believe that implementation of the current plan, which took extensive time, resources, input, and compromise from diverse stakeholders, is the clear way to move forward, as opposed to beginning another multi-year plan amendment process which we believe would not be in the best interest of any of the stakeholders as it would cause significant increased conflict.

We appreciate the opportunity to work with the Forest Service, the Ruckelshaus Institute working group, and livestock grazing permittees to find pragmatic solutions to prairie dog management. It is our hope that social conflicts can be reduced and all stakeholder interests addressed so together, we can move forward with our shared goal of maintaining grassland ecosystem health at Thunder Basin.

Thunder Basin National Grassland is one of the best remaining intact prairie ecosystems in the North American Great Plains. Prairie vestiges such as TBNG have become too few, small, degraded, and isolated from each other, which has contributed to significant losses in biological diversity. As conservationists, we are working to restore fully functioning, intact prairie ecosystems that sustain the array of wildlife associated with them. This ecosystem is home to many increasingly rare species of the prairie, including ferruginous hawk, swift fox, mountain plover, and burrowing owl. The reason these species flourish at Thunder Basin is due to the large complex of black-tailed prairie dog colonies found here, a once far more common occurrence across the Great Plains.

In addition, TBNG – lands within the public trust – are for multiple use, not just for those who live in proximity with ranching operations. Forest Service mandates account for managing for biodiversity as well as all stakeholder interests of these lands. The conservation of wildlife and the ecological health of this grassland is a shared value by all interests, prairie dogs aside.

Our request is simple: Implement the current TBNG Land and Resource Management Plan and prairie dog management strategy.

Our request includes:

- Maintaining Category 1 as key prairie dog habitat (with the minimum goal of 18,000 acres of active prairie dog colonies) and management area 3.63 for future recovery of the black-footed ferret;
- Utilizing nonlethal tools for prairie dog control measures where required or appropriate;
- Addressing other stakeholder concerns in compliance with plan standards and guidelines.

For nearly 12 years, our organizations have dedicated time, energy, and resources to prairie dog management at TBNG. Collectively, we have invested over $200,000 toward a host of conservation efforts on TBNG, including the relocation of prairie dogs away from private land boundaries into the core conservation area when acreage was below objective, as well as sylvatic plague mitigation and sylvatic plague research. To this end, we are advocating for solutions to address the current social climate related to management and control of prairie dogs. As Ms. Buchanan acknowledged during our meeting, the plan has not been properly executed given other Forest Service priorities in recent years. We are hopeful that implementation of the prairie dog and habitat management tools as outlined in the compromise plan, in addition to the collaborative vegetation management project currently being planned in one grazing allotment, will create more of a culture of collaboration and trust among the Forest Service and currently disparate stakeholders.

Our organizations are interested in continuing to work with the Forest Service to provide resources for the current plan’s implementation, including resources for willing landowners and grazing permittees to partner on habitat and wildlife restoration efforts on TBNG. Our key tasks provide for a successful approach toward these goals, as Forest Service partners.
These include:

- Working with the Forest Service and stakeholders to apply nonlethal prairie dog management practices;
- Identifying priority areas for habitat and wildlife restoration projects;
- Reaching out to landowners for cooperative agreements (along with securing resources) to implement habitat and wildlife restoration projects, such as with the Fiddleback Ranch, in cooperation with the Forest Service and Converse County;
- Assisting with black-footed ferret recovery when appropriate.

We believe these relationships and collaborations – working together for positive outcomes – are critical to moving forward for the health of TBNG.

We have heard directly that some stakeholders want a new plan amendment so that all mention of black-footed ferret recovery can be removed and fewer acres of prairie dogs maintained. However, these goals are clearly one-sided, unreasonable, and in violation of laws and policies requiring federal agencies to assist with listed species recovery. In addition, removing language or reference to black-footed ferrets and the potential for their reintroduction will not lead to more rainfall nor solve the current social issue with prairie dogs. Furthermore, the Forest Service does not have the funding to reduce prairie dogs down to the minimum acres required to be maintained under the current plan, let alone reduce even further. There is no need for a new plan amendment.

We firmly believe that moving forward with a new plan amendment process would be counter to achieving solutions and reducing conflict. The current plan and prairie dog amendment took 10 years to develop and included extensive public input and an appeals process. A directive for a new amendment would result in yet another costly and time intensive process for the Forest Service and for stakeholders and would inevitably lead to additional appeals and public controversy, stalling currently planned on-the-ground projects, adding more years to the already looming timeline, and delaying the important work to facilitate habitat improvements and prairie dog management on TBNG.

Instead of wasting valuable resources on an unnecessary and unworkable plan amendment, the Forest Service could work to reduce the social divide with prairie dog management. The full potential of the current plan has not been implemented.

Solutions must center on land uses and resource management activities that are conducted in a manner that is compatible with maintaining suitable black-footed ferret habitat. Standards listed in the TBNG Plan for (Chapter 3, Management Area 3.63, General – 1 (revised) include: 1) *Authorize only those uses and activities that do not reduce the suitability of the area as black-footed ferret reintroduction habitat; and 2) Manage all prairie dog colonies within this Management Area as though they were occupied by black-footed ferrets, and apply all Standards and Guidelines as though black-footed ferrets occupy all colonies*.

The 2009 plan amendment provides for the following:

- Category 1 Prairie Dog Habitat will have a "management objective of at least 18,000 acres of active prairie dog colonies."
- After exceeding 18,000 acres, any "use of rodenticide on federal lands may only be employed within ½ mile of the TBNG boundary and only in cases where appropriate and available nonlethal options have been tried and found ineffective for changing the rate and direction of colony expansion."
- Category 2 Prairie Dog Habitat have a combined (4W, Middleton, North 450, South Cellers and Piney Creek) management objective of 9,000 acres of active prairie dog colonies.

The current plan includes a suite of nonlethal measures (e.g., translocation, vegetative barriers, structural barriers, etc.) and lethal tools (rodenticide, shooting, etc.) to manage prairie dogs when they are below or above objective; in addition, the plan includes options for improving and restoring grassland habitat (e.g., cactus management, fire, etc.). Categories 1 and 2 represent a small portion of the overall acres of TBNG. The rest – upwards of 450,000 acres – is widely open to prairie dog lethal control. An estimated 100,000 prairie dogs are slated to be poisoned with the proposed 10,000 acres of poisoning in 2017 (10 prairie dogs per acre is widely accepted as a conservative estimate). This will also impact an unknown number of associated species. Under no circumstances should Rozol be approved for use within TBNG boundaries for the myriad of impacts it has on nontarget species.

We request the following actions:

- Immediately reinstate the shooting closure in Category 1 and Management Area 3.63;
- Ensure that Forest Service and county prairie dog control do not violate the TBNG plan;
- Prohibit the use Rozol on Forest Service lands; Rozol has proven impacts to nontargeted wildlife (please see appendix); the Western Association of Fish and Wildlife Agencies and the U.S. Fish and Wildlife Service also strongly oppose its use;
- Continue to encourage and help support habitat restoration projects with landowners;
- Provide for better inclusion of our organizations in discussions surrounding TBNG's prairie dog ecosystem.

We are currently soliciting the following for your information gathering efforts:

- Vegetation transects in the 3.63/Category 1 areas.
- 2) A prairie dog colony inventory and map (Thunder Basin Grassland Prairie Ecosystem Association).
- 3) The biological capability document for TBNG as a suitable black-footed ferret reintroduction site.

We include with this letter a map of prairie dog susceptibility to shooting beyond roads, eight articles related to the use of Rozol, showing impacts to non-target wildlife species, along with a summary of main points of those papers (complied by the Prairie Dog Coalition), and a memo on the current conditions relative to plague, with responses by Dr. David Augustine, USDA Agricultural Research Services.

We value the opportunity to provide comment for sustainable habitat and wildlife management practices on TBNG and toward our shared value of its ecological health. We would like to meet with you both as soon as possible to continue this important dialogue in person and provide additional ideas for solving conflicts while managing natural resources. Please let us know when you are available to meet.

Sincerely,

Chamois L. Andersen

Executive Summary

This document presents the Agency's assessment of potential risks to birds and nontarget mammals from 9 rodenticides, including 3 second-generation anticoagulants (brodifacoum, difethialone, bromadiolone), 3 first-generation anticoagulants (diphacinone, chlorophacinone, warfarin), and 3 non-anticoagulant compounds (zinc phosphide, bromethalin, cholecalciferol). These rodenticides are predominantly used to control commensal rats and mice in and around buildings, transport vehicles, and in sewers. Some, mainly zinc phosphide, chlorophacinone, and diphacinone, also have products registered for other outdoor uses against other rodent and small mammalian pests. A major concern in using rodenticides is that they are not selective to the target species; birds and nontarget mammals that feed on grain-based baits (pellets, meal, treated grains, wax blocks) or meat-based, vegetable, or fruit baits are potentially at risk. The available information from laboratory and pen studies, field studies, control programs, reported incidents, and toxicokinetics also indicates that a variety of avian and mammalian predators and scavengers are potentially at risk from consuming animals poisoned with some of these rodenticides.

The assessment focuses on the potential primary and secondary risks to birds and nontarget mammals posed by applications of these 9 rodenticides (11 baits) to control rats and mice in and around buildings (commensal use) and in field and other outdoor settings to control various rodent and other small mammalian pests. Risk is a function of exposure and hazard (toxicity), and data are available to estimate toxicity based on laboratory acute and secondary-hazard tests. However, typical use information used to estimate nontarget organism exposure, such as amount of active ingredient or formulated product applied per unit area, is not available for commensal uses. Thus, exposure estimates are largely based on the amount of active ingredient available per kilogram of the formulated bait (mg ai/kg bait). An assumption is made in most OPP/EFED risk assessments that birds and nontarget mammals are likely to be exposed to the pesticide via consumption of contaminated foods. This assumption is well established for rodenticides, for which ingestion of the formulated bait is the route of exposure.

Refining the exposure assessment to establish a quantitative measure of likelihood of exposure and effects would require a much more extensive data set than registrants have submitted for their rodenticides and for the nontarget species potentially at risk. The Agency provided the preliminary risk assessment to rodenticide registrants in October, 2001 and posted it in the EDocket on EPA's website for public comments from January 29 to May 30, 2003. No additional data or relevant information to refine the exposure assessment has been provided by the registrants or other stakeholders. Nevertheless, the existence of substantial incident data along with liver-residue analysis confirms that birds and nontarget mammals are being exposed and adversely affected by applications of rodenticide baits. The fact that numerous species of birds and mammals, including predators and scavengers, have been found exposed to these baits indicates that both primary and secondary exposures are occurring.

The risk conclusions are based both on the lines of evidence of the available data and comparative analysis modeling. Each rodenticide is ranked or categorized and compared to the other rodenticides according to the following criteria: (1) overall potential risk; (2) potential primary risk to birds; (3) potential primary risk to nontarget mammals; (4) potential secondary risk to avian predators and scavengers; and (5) potential secondary risk to mammalian predators and scavengers. Conclusions are presented below.

- Brodifacoum and difethialone stand out as the two rodenticides posing the greatest potential overall risk to birds and nontarget mammals, followed by bromadiolone and diphacinone. Zinc phosphide also ranked high for overall risk based on the comparative analysis modeling, primarily because of high potential primary risks.

- Brodifacoum, difethialone, and zinc phosphide pose the greatest potential primary risks to birds that eat bait. A single zinc phosphide or brodifacoum bait pellet provides more than an LD50 dose for a small bird. In contrast, a small bird would need to eat more than twice its body weight in bait pellets to ingest a comparable dose of a first-generation anticoagulant in a single feeding.

- Rodenticide baits are formulated to be lethal to small mammals, and they are not selective to the target species. All baits pose a high potential primary risk to nontarget mammals that eat bait. However, the first-generation anticoagulants likely pose less risk to mammals that only occasionally feed on 1 or just a few bait pellets, because they are more rapidly metabolized and generally must be eaten for several days to provide a lethal dose.

- Brodifacoum and difethialone pose the greatest potential risks to avian predators and scavengers that feed on target or nontarget animals poisoned with bait. The available data indicate that the first-generation anticoagulants are less hazardous than the more highly toxic and persistent second-generation anticoagulants.

- Mammalian predators and scavengers are at risk from feeding on animals poisoned with anticoagulant baits. Although the non-anticoagulant rodenticides appear to be much less hazardous to secondary consumers, confirmatory data are still needed to make this assumption for bromethalin and cholecalciferol baits.

- The available toxicokinetic data indicate that the second-generation anticoagulants are considerably more persistent in animal tissues than are the first-generation anticoagulants, and bioaccumulation may increase whole-body residues with repeat feedings.

- More than 300 documented wildlife incidents attest to exposure of birds and nontarget mammals, including endangered species, to some rodenticides, especially brodifacoum (244 incidents). Brodifacoum residue has been detected in liver tissue of 27 of 32 endangered kit foxes screened for rodenticide residues from 1999 to 2003. Birds in which rodenticides are most frequently detected include owls, hawks, eagles, and crows; mammals include wild canids and felids, tree squirrels, raccoons, deer, and others.

- The U. S. Fish and Wildlife Service issued a Biological Opinion in 1993 that includes reasonable and prudent alternatives and measures for protection of 29 mammalian and 11 avian threatened or endangered species potentially at risk from exposure to 8 of these rodenticides. These issues will be addressed by OPP's Endangered Species Protection Program.

- Adverse effects of possible sublethal exposure are unknown, and avian and mammalian reproduction studies are needed to establish a no-observable-adverse-effects concentration (i.e., "toxicity threshold") for each rodenticide.

A number of factors contribute uncertainty to the assessment. Those that appear to contribute the most uncertainty are: (1) missing data, including acute, chronic, and secondary toxicity as well as retention of some active ingredients in the liver, blood, and other body tissues; (2) the variable quality and quantity of existing data on metabolism and retention times in rodents and nontarget species; (3) specific use information by formulation, including typical amounts applied by use site, seasonally, and annually; distances applied from buildings; amounts used in rural versus urban areas; use by Certified Applicators versus homeowners and other non-certified applicators; and other such relevant information; (4) information on the number and species of birds and nontarget mammals frequenting baited areas and their likelihood of their finding and consuming bait or poisoned primary consumers in the various use areas; (5) methods to determine liver concentration(s) and total body burdens of rodenticide that would corroborate death or even if such a cause-effect relationship is appropriate (e.g., the "threshold of toxicity" concentration); (6) not accounting for the impacts of sublethal effects on reproduction and nontarget mortality (e.g., clotting abnormalities, hemorrhaging, stress factors including environmental stressors, such as adverse weather conditions, food shortages, and predation); (7) not accounting for bioaccumulation of repeated sublethal exposures to bait or poisoned rodents utilized as food by predators and scavengers; and (8) lack of incident reporting.

Table of Contents

Potential Risks of Nine Rodenticides to Birds and Nontarget Mammals: a Comparative Approach

Presented here is the Agency's assessment of rodenticide risks to birds and nontarget mammals. The 9 rodenticides include those addressed in the Reregistration Eligibility Decisions (REDs) for the Rodenticide Cluster (brodifacoum, bromadiolone, chlorophacinone, diphacinone, bromethalin; EPA 1998a), Zinc Phosphide (EPA 1998b), and Warfarin and its Sodium Salt (EPA 1991a). Difethialone and cholecalciferol, which are not subject to the current reregistration process but are alternative compounds for rat and mouse control, also are included. All 9 rodenticides are available to the public "over the counter" as grain-based food baits for control of commensal rats and mice, predominantly the Norway rat (*Rattus norvegicus*), roof rat (*R. rattus*), and house mouse (*Mus musculus*), in and around buildings, transport vehicles, and inside sewers. Some products, mostly "restricted-use" (i.e., available only to Certified Applicators) products containing zinc phosphide, chlorophacinone, or diphacinone, also are available for control of various rodent and other small mammal pests in field and other outdoor settings.

The purpose of this assessment is to evaluate potential primary and secondary risks of each rodenticide and to compare and rank them among compounds. The Agency's concern about risks to birds and nontarget mammals is based on several factors, including (1) the high acute toxicity of these rodenticide baits, which are designed to be lethal to small mammals; (2) risk estimates, based on available exposure and toxicity data, that exceed Agency levels of concern (LOCs); (3) mortality of birds and nontarget mammals exposed to rodenticide baits or poisoned prey in laboratory, pen, and field settings; (4) retention time of residues in body tissues of primary consumers, and (5) numerous reported incidents that indicate exposure of numerous nontarget species, including avian and mammalian predators and scavengers. Rodenticide baits are formulated to be lethal to rodents and a few other small mammals, and they are not selective to target species. Many factors influence which nontarget animals might be exposed to baits, but many birds and mammals are attracted to seeds and grains and are likely to consume grain-based baits. A few commensal baits also contain flavorizers such as fish, molasses/peanut butter, or apple, and some field baits are formulated with foods other than grains (ground meat, canned or dry meat-based pet foods, fruits, vegetables) that might appeal to carnivores and omnivores. Rodenticide baits also pose potential secondary risks, because predators and scavengers are likely to be attracted to dead or dying rats, mice, and poisoned nontarget animals.

Risk is a function of exposure and hazard (toxicity). Data are available to estimate toxicity based on laboratory acute-toxicity and secondary-hazard tests. Use information, such as amount of active ingredient or formulated product applied per unit area per application, is typically used to estimate nontarget organism exposure but is not available for most rodenticide uses. Therefore, exposure estimates are largely based on the amount of active ingredient available per kilogram of grain-bait formulation (mg ai/kg bait, or ppm ai). See the "*Exposure*" section under

"*Use and Exposure Considerations*" for additional discussion of the differences in estimating expected environmental concentrations (EECs) for rodenticide food baits versus other types of pesticide applications (e.g., foliar sprays).

Risk conclusions are presented in tabular and graphical form based on two analyses of the available data. One analysis is a ranking of potential risks of each rodenticide based on a comparative analysis model. That methodology is explained in more detail in the "*Comparative analysis model*" section of the assessment and in Appendix C. The other analysis uses a lines-of-evidence approach in which the available quantitative and qualitative information is evaluated and each rodenticide assigned a rating of high, moderate, or low for primary risk to birds, primary risk to mammals, secondary risk to birds (avian predators and scavengers), and secondary risk to mammals (mammalian predators and scavengers). For primary risks, the amount of bait and number of bait pellets that need to be eaten to provide an LD50 dose (i.e., dose expected to be lethal to 50% of the individuals in a population) are calculated for 3 size classes (25 g, 100 g, 1000 g) of birds and mammals. Dietary risk quotients that compare the amount of toxicant (ppm ai) in a bait to the dietary toxicity (LC50) of the rodenticide also are used as a comparative index of primary risk. For secondary risks, these methods cannot be used, because LD50 and LC50 data are not available for predatory species of birds and mammals. Consequently, assessments of secondary risk are made based on mortality and other adverse effects reported in laboratory and field studies and operational control programs, incident reports, toxicokinetic data, and residues reported in primary consumers. This approach is in accord with EPA's risk-assessment guidelines (EPA 1998c), which assert that professional judgement or other qualitative evaluation techniques are appropriate for ranking risks into categories such as low, medium, and high when exposure and effects data are limited or are not easily expressed in quantitative terms. A lines-of-evidence approach for improving field-study interpretation also has been advocated by the Avian Effects Dialogue Group (Rymph 1994).

The information used in this assessment was obtained from studies submitted to the Agency in support of registration/reregistration, from published literature and personal communications, and from the Agency's Ecological Incident Information System (EIIS). For some rodenticides, few data are available other than acute oral (LD50) and dietary toxicity (LC50) values for the Agency's required test species: northern bobwhite (*Colinus virginianus*), mallard (*Anas platyrhynchos*), and laboratory rat (*R. norvegicus*). The quality and quantity of data available on metabolism and retention times in rodents and secondary toxicity to nontarget birds and mammals vary among the rodenticides, but the available data are sufficient to identify the most persistent and hazardous compounds.

Modes of action

The anticoagulant rodenticides are vitamin-K antagonists that disrupt normal blood-clotting mechanisms and induce capillary damage (Pelfrene 1991). Death results from hemorrhage, and exposed animals may exhibit increasing weakness prior to death. Behavior also may be affected (Cox and Smith 1992). The anticoagulants are typically grouped into "first-generation" (warfarin, chlorophacinone, diphacinone) and "second-generation" (brodifacoum, bromadiolone, difethialone) compounds. Second-generation anticoagulants tend to be more acutely toxic than are the first-generation anticoagulants, and they are retained much longer in body tissues of primary consumers. They generally provide a lethal dose after a single feeding, although death is usually delayed 5 to 10 days and animals continue feeding. In contrast, the first-generation compounds, because they are less acutely toxic and more rapidly metabolized and/or excreted, generally must be ingested for several days to provide a dose lethal to most individuals. Diphacinone and chlorophacinone may kill some animals in a single feeding, but multiple feedings are generally needed for sufficient population control (Timm 1994). The structural relationships of these rodenticides and some of their physical/chemical properties are presented in Attachment A.

The non-anticoagulant rodenticides belong to 3 chemical classes that differ from one another and the anticoagulants in their mode of action. They can provide a lethal dose from a single feeding but are much less likely than the anticoagulants to be retained in toxicologically significant amounts in body tissues of primary consumers. Bromethalin, a diphenylamine, is a neurotoxicant that causes respiratory arrest from inadequate nerve impulse transmission after fluid build-up and demyelination inside the central nervous system (Spaulding and Spannring 1988, Hyngstrom et al. 1994). Further feeding is inhibited after ingestion of a lethal dose, and death typically occurs within 2 days. Zinc phosphide is an inorganic compound whose toxicity results from liberation of phosphine gas from reaction of the active ingredient with water and acid in the stomach (Hyngstrom et al. 1994). Death can occur within a few hours of ingestion. Cholecalciferol is a sterol (vitamin D_3). Its ingestion results in hypercalcemia from mobilization of calcium from bone matrix into blood plasma (Pelfrene 1991). Death can occur 3 to 4 days after a single feeding.

Terms and definitions

Dietary toxicity test: To support registration of a pesticide, the Agency's Office of Pesticides Program (OPP), Environmental Fate and Effects Division (EFED), requires 2 avian dietary (LC50) studies: one using northern bobwhite chicks as test animals and the other using mallard ducklings (40 CFR §158.490 Wildlife and Aquatic Organisms Data Requirements, Guideline Reference No. 71-2). The dietary test consists of a 5-day exposure period during which toxicant is added to the birds' diet at 5 concentrations using 10 test animals (5 males, 5 females) per concentration. The exposure period is followed by a 3-day observation period; however, because death is delayed for several days after exposure to an anticoagulant, the post-treatment observation period has been extended 15 days or more for those compounds. The test material is the technical grade of the active ingredient.

Dietary toxicity testing is not usually conducted for mammals, although the Agency may require a wild-mammal toxicity test (40 CFR §158.490 Wildlife and Aquatic Organisms Data Requirements, Guideline Reference No. 71-3) if deemed necessary. Because rodenticides are formulated to be lethal to mammals and the Agency requires efficacy testing for all rodenticide end-use products (40 CFR §158.640 Product Performance Data Requirements, Guideline Reference No. 96-10 and 96-12), EFED has not required a wild-mammal toxicity test for any of the rodenticides. However, EFED has found reports for laboratory-rat dietary tests for 5 rodenticides tested by the Agency's former Toxicology Unit, Chemical and Biological Investigations Branch. During 1980 and 1981, McCann et al (1981) developed a short-term dietary LC50 test for small mammals. They exposed 5-male and 5-female immature albino Norway rats (Wistar strain) per test concentration to dry diet offered *ad libitum* and treated with one of 17 chemicals pesticides, mostly organophosphate and carbamate pesticides. The tests consisted of a 5-day acclimation period, a 5-day exposure period, and a post-treatment observation period lasting at least 9 days. Following submission of the paper for publication, testing continued and included 5 rodenticides: brodifacoum, bromadialone, chlorphacinone, diphacinone, and warfarin. Results of these tests were not published but the test reports are available, and multiple studies exist for each of those 5 rodenticides.

LC50: Median lethal concentration. A statistically estimated dietary concentration expected to be lethal to 50% of the test animals. The LC50 is expressed in ppm. The 95% confidence intervals are reported when available.

Acute oral toxicity test: For individual pesticides, EFED requires one acute oral (LD50) test for birds, using either the northern bobwhite or the mallard as the test species (40 CFR §158.490 Wildlife and Aquatic Organisms Data Requirements, Guideline Reference No. 71-1). Data are available for both species for some rodenticides. The toxicant is orally administered via capsule or gavage in a single dose to adult animals. The test required by the Agency includes 5 concentrations, with 10 test animals (5 males, 5 females) per concentration. Unless otherwise noted, the test material is the technical grade of the active ingredient. OPP's Health Effects Division (HED) also requires acute oral testing with the laboratory rat (40 CFR §158.340 Toxicology Data Requirements, Guideline Reference No. 81-1) and sometimes has data for other mammals (e.g., laboratory mouse, dog). EFED uses these data in the mammalian risk assessment.

LD50: Median lethal dose. A statistically estimated oral dose expected to be lethal to 50% of the test animals. The LD50 is expressed in mg of active ingredient per kg of body weight of animal. The 95% confidence intervals are reported when available.

> ***Note:*** Some LD50 values for birds and mammals were obtained from the literature. These are considered supplemental data, because the test concentrations, number of animals tested, and confidence intervals often are not reported or may not meet Agency test guideline requirements. Calculations of risk quotients and estimates of ingestion of active ingredient from bait consumption utilize the toxicity data reviewed and accepted by the Agency.

Primary Risk: Risk to target or nontarget organisms that consume bait.

Secondary Risk: Risk to predatory or scavenging birds or mammals that feed on target or nontarget animals that ate bait.

Dietary Risk Quotient (RQ): An index of exposure to dietary toxicity (LC50), where exposure is expressed as the amount of rodenticide in food (ppm ai in bait for primary exposure or in target species for secondary exposure). Risk presumptions are based on whether or not RQs exceed OPP's Levels of Concern. RQs do not quantify risk, but they are useful for comparing risks among alternative compounds (ECOFRAM 1999).

Level of Concern (LOC): A presumption of risk is made if an RQ equals or exceeds the Agency's LOCs: 0.5 for acute risk to non-endangered species and 0.1 for acute risk to endangered species. Additionally, an RQ that equals or exceeds 0.2 triggers consideration of "restricted-use" classification to mitigate acute risk.

***A note on scientific names*:** The scientific name of a species is provided after the first mention of its common name in the text. A complete list of common and scientific names of the birds and mammals referred to in the document is included in Attachment B.

Comparative analysis model

A comparative analysis model also is used to rank and compare potential primary and secondary risks. The underlying methodology is a simple multi-attribute rating technique, or SMART (Goodwin and Wright 1998). SMART is adapted for comparing potential risks among rodenticides based on a number of measure-of-effect values for primary and secondary risk to birds and mammals. Each type of risk is quantitatively evaluated by the following measures of effect:

Primary risk to birds:	dietary RQ (mean value if more than one dietary RQ available); inverse of the number of bait pellets needed for a 100-g bird to ingest an LD50 dose in a single feeding
Primary risk to mammals:	inverse of the number of bait pellets needed for a 100-g mammal to ingest an LD50 dose in a single feeding
Secondary risk to birds:	mean % mortality from secondary toxicity studies; retention time (days) of active ingredient in the blood; retention time (days) of active ingredient in the liver
Secondary risk to mammals:	mean % mortality from secondary toxicity studies; retention time (days) of active ingredient in the blood; retention time (days) of active ingredient in the liver

Retention time is not a direct measure of effect for secondary risk to birds and mammals, but it is an important contributing factor. The combination of mean % mortality from secondary laboratory toxicity studies, which characterizes the secondary toxicity from short-term exposures, and available data on retention time in both blood and liver, which indicates how long toxic levels can persist in target animal tissues, can characterize the secondary risk to birds and mammals.

When faced with a number of alternatives and a number of types of risk with measures of effect, SMART prescribes the following: (1) each alternative rodenticide is rated on each measure of effect; (2) each measure of effect is assigned a measure of importance to the risk assessor; and (3) a summary score for each alternative rodenticide is calculated as a weighted average of the ratings, where the weights represent the relative importance of the measure of effect for each type of risk. The higher the resultant summary score, the higher the potential risk for that rodenticide.

The following basic equation is used to calculate the summary values for the risk comparison:

$$\text{Summary Value}_{(\text{scale from 0 to 10})} = 3\ ƒ(\mathrm{ME}_i)(\mathrm{ME}_{max})^{-1}„\ ƒ(\text{Weight})\ (3\text{Weights})^{-1}„\ (10)$$

where "ME_i" is the measure of effect value for a rodenticide and "ME_{max}" is the maximum ME for all rodenticides; "Weight" is the importance value, from 10 to 0, placed on each measure of effect, with high = 10 to 6.67, medium = 6.68 to 3.33, and low = 3.34 to 0; "3Weights" is the sum of all the weights for all the measures of effect. All measures of effect, except two, are assigned a "high" (10 out of 10) measure of importance for the rodenticide analysis. The half-life in blood and liver are each given a weight of "low" (2.5 out of 10) for analyzing secondary risks to birds and mammals, so that the overall importance of the persistence data (2.5 x 4=10) equals but does not exceed that of the mortality data.

A sensitivity analysis also is performed to evaluate how changes in each measure-of-effect value could affect the overall summary risk results. Each measure-of-effect value is separately decreased and increased by 50% (154 variations). To further examine the robustness of the rankings, selected high and low summary risk values are subsequently changed by up to ±99%. Further details of the SMART analysis, including the input values for measures of effects, are presented in Attachment C.

The methodology used in the comparative analysis model is similar to that used in the Agency's "Comparative Analysis of Acute Risk From Granular Pesticides" (EPA 1992) and "A Comparative Analysis of Ecological Risks from Pesticides and Their Use: Background, Methodology, Case Study" (EPA 1998d); both were reviewed by a FIFRA Scientific Review Panel. Concerning the latter analysis, the Panel noted the many scientific uncertainties in the method, yet agreed that it was a useful screening tool that provides an estimate of relative risk. The Panel made a number of helpful suggestions to improve the utility of the method, most of which are included here. In this analysis, a risk quotient (RQ), calculated as the ratio of toxicant potentially ingested to the inherent toxicity of the rodenticide, is used to compare potential primary risks to birds and nontarget mammals. RQs are compared among rodenticide baits based on the amount of bait and number of bait pellets that birds or nontarget mammals of various sizes would need to eat to ingest an acute oral (LD50) dose. Dietary data (LC50) also are available, and RQs based on bait concentration and avian dietary toxicity are compared among the rodenticides. As noted by the Ecological Committee on FIFRA Risk Assessment Methods (ECOFRAM 1999), RQs do not quantify risk but are useful for comparisons among alternative compounds. EPA's "Guidelines for Ecological Risk Assessment" (EPA/630/R-95/002F, 1998c) also notes that quotients provide an efficient, inexpensive means of identifying high- or low-risk situations that can allow risk management decisions to be made without the need for further information.

Use and Exposure Considerations

This assessment focuses on the potential primary and secondary risks to birds and nontarget mammals posed by applications of these 9 rodenticides to control rats and mice in and around buildings (commensal uses) and elsewhere outdoors (field uses) to control rodents and certain other mammalian pests. As previously noted, rodenticide products for field use (except those for underground baiting of pocket gophers and moles) are currently registered as "restricted-use" or restricted-use classification is being imposed during reregistration. This classification provides increased protection of birds and nontarget mammals, because baits may only be applied by a Certified Applicator or someone directly supervised by a Certified Applicator. These applicators are trained to closely follow label use directions and restrictions that may help limit exposure, and thus risk, to nontarget organisms. However, even with this increased protection, there remains a potential risk to nontarget organisms from these uses since the rodenticides are lethal to birds and mammals, are not selective, and their grain-based bait formulations may be highly attractive to many nontarget organisms.

Product labels for commensal uses specify that applicators should comply with the following *DIRECTIONS FOR USE*:

> "Apply bait in locations out of reach of children, pets, domestic animals and nontarget wildlife, or in tamper-resistant bait stations. These stations must be resistant to destruction by dogs and by children under 6 years of age, and must be used in a manner that prevents such children from reaching into bait compartments and obtaining bait. If bait can be shaken from stations when they are lifted, units must be secured or otherwise immobilized. Even stronger bait stations are needed in areas open to hoofed livestock, raccoons, bears, or other potentially destructive animals, or in areas prone to vandalism."

To what extent applicators comply with these use directions or even use bait stations is unclear. As noted in Pesticide Regulation (PR) Notice 94-7 (EPA 1994), "Nonprofessional users (i.e., the "general public") often apply baits in open containers or in ready-to-use, non-protective, packaging. Bait stations typically are not offered for sale at the outlets where nonprofessional users buy rodenticides. Attempts to market ready-to-use (bait-filled) protective rodenticide bait stations to the general public have not been reported as commercially successful ventures." Tamper-resistant or stronger bait stations exclude mammals larger than adults of the target species, because the entrance holes to the bait compartment are designed to be no larger than necessary. However, mammals smaller than the target species can enter bait stations and feed on bait and are at risk. Because target species leave bait stations after feeding, bait stations likely have little if any impact on secondary exposure of predators and scavengers that feed on dead or dying rodents.

The commensal use in and around buildings is common to all 9 rodenticides. However, difethialone and bromadiolone can be applied only inside of buildings and similar manmade structures in non-urban areas. Indoor applications likely reduce primary exposure of nontarget organisms. Nevertheless, rats or mice that eat bait, especially an anticoagulant bait, do not die for several days after ingesting a lethal dose. Because these target species may move outdoors before dying, some predators and scavengers might still be exposed as a result of indoor application.

Field uses involve a variety of bait applications, including broadcasting, spot-baiting, or application of bait in some type of bait station. Depending on the use, broadcasting is done by hand, ground-based mechanical spreader, or by air. Some, but not all, broadcast applications limit the number of treatments that can be made and specify an interval between applications. Some uses also allow spot baiting, in which bait is placed by hand in small pile or scattered across smaller areas (e.g., bare ground around burrow openings) at a treatment site. Bait stations should be covered or enclosed. For some uses an uninterrupted supply of bait is maintained for 1 to 4 weeks, whereas for others no time interval is specified. Bait stations are usually placed on the ground in areas frequented by the target species, such as by burrow openings, runways, or feeding areas. Floating bait stations are used for some target species (e.g., muskrats). In some situations, customized bait stations have been developed to exclude nontarget species that are smaller than individuals of the target species. Elevated and "T" bait stations have been developed to reduce exposure of some nontarget species, such as deer mice (Erickson et al. 1990) and kangaroo rats (California Department of Pesticide Regulations
http://www.cdpr.ca.gov/docs/es/espdfs/baitsta1.pdf
http://www.cdpr.ca.gov/docs/es/espdfs/baitsta2.pdf).
More research is warranted to devise means of selectively applying baits to protect nontarget species while adequately maintaining efficacy against target species.

For control of pocket gophers and moles in lawns, golf courses, and other noncrop areas, bait is applied in subsurface runways or deeper underground tunnels and is not exposed on the ground surface. Hand baiting is done using a mechanical probe or similar device to locate an underground runway. Bait is inserted through the probe hole, and the hole is then sealed with sod or a stone. In some situations a mechanical burrow-builder is used by a Certified Applicator to construct artificial pocket-gopher burrows into which bait is mechanically inserted at 4- to 5-foot intervals.

Exposure

Exposure is an integral component of ecological risk. Many factors influence which nontarget animals might be exposed to rodenticide baits. They include the species found in and around treatment areas, species' food habits and foraging behavior, home range, propensity to feed in and near human buildings, bait availability (e.g., quantity, how applied, where applied, when applied), and other such factors. However, there is no doubt that many birds and nontarget mammals are attracted to and will consume grain-based foods. Additionally, many nontarget predators and scavengers feed on rats, mice or other target species. They are not likely to avoid feeding on rats, mice, voles, ground squirrels, or other animals that have eaten bait.

EFED's exposure assessment for the rodenticides differs from that for most other pesticides. For foliar-applied pesticides, EECs on potential food items (grasses, seeds, insects) of birds and mammals are extrapolated from field-residue data compiled by Hoerger and Kenaga (1972) as modified by Fletcher et al. (1994). The maximum EEC on avian and mammalian food items is 240 ppm on short grass, 135 ppm on broadleaf plants and insects, and 15 ppm on seeds for every 1.0 lb ai applied per acre. EECs for granular formulations or soil-applied sprays are typically based on the number of LD50s applied per square foot. For each specific crop or use site, EECs depend on the label-specified application rate (lb ai/acre), number of applications, interval between applications, and the application method. However, for a rodenticide, the bait itself is the potential food item of concern. Thus, the amount of active ingredient in the formulated bait is used as the EEC. This information is used to estimate the amount of bait and number of bait pellets that birds and mammals of various sizes need to consume in a single feeding to obtain a dose expected to be lethal to 50% of the individuals in the population (i.e., LD50 dose). Estimates of food-ingestion rates (g dry matter per day) were determined from established allometric equations presented in EPA's Wildlife Exposure Factors Handbook (EPA 1993). The concentrations of active ingredient in the bait pellets are also used to estimate initial dietary exposure (mg ai per kg in bait) used to calculate avian and mammalian dietary risk quotients.

These estimates of acute primary exposure of nontarget organisms are not appropriate for estimates of secondary exposure. Secondary exposure estimates are considerably more complex and require consideration of residues in tissues of target organisms that are commonly consumed by predators and scavengers, as well as knowledge of what residue level will result in mortality or adverse chronic effects. Moreover, it is important to know how long the residue persists in body tissues. A number of laboratory tests using avian and mammalian predators or scavengers are available to assess mortality from secondary exposure resulting from consumption of prey animals that had been exposed to rodenticides. Design and methodology vary among studies, adding unknown variability to the results and analysis. Pending development of standard methods and testing requirements for such studies, these tests provide the best data available. The mean percent (%) mortality for these bird and mammal laboratory tests are used to estimate both secondary exposure and hazard. Because retention time in tissues consumed by scavengers and predators is an important factor in estimating secondary exposure and potential risk, available retention times (half-life in days) of rodenticide in liver and blood are also factored into secondary exposure and risk estimates. A discussion of residue levels in tissues of target species is included in the assessment. Uncertainties remain in establishing levels indicative of mortality or other adverse effects in nontarget organisms.

In most pesticide assessments the assumption is made that nontarget birds and mammals are likely to be exposed to the pesticide without attempting to establish a quantitative measure of this likelihood. This assumption is used in this assessment for these 9 rodenticides and 11 bait formulations. The existence of substantial incident data along with liver residues corroborates the assumption that nontarget birds and mammals are exposed and adversely affected by the use these rodenticide baits. The fact that numerous species have been found exposed to these rodenticide formulations, including predators and scavengers, indicates that both primary and secondary exposure occurs.

Target species, use sites, and rodenticide usage

Control of commensal rats and mice is the predominant use of most of the rodenticides. Most products for rat and mouse control are formulated as grain-based pellets or, for sewer use, as paraffinized food blocks. Several rodenticides also are registered for field and other outdoor uses (Table 1). Zinc phosphide is used to control ground squirrels (*Spermophilus* spp.), prairie dogs (*Cynomys* spp.), pocket gophers (Geomyidae), and moles (Talpidae) in addition to commensal rats and mice. Most are pellets or grain baits, but meat (ground meat, canned dog or cat food, dry meat-based pet food), sunflower seed, and fruit or vegetable (carrots, sweet potatoes, dandelions, alfalfa, beet tops, cabbage, potatoes, grapes, mulberry, apricots, figs, nuts, apples, pears) baits also are used against some target species. Nine states also have individual state registrations (FIFRA §24c Special Local Need [SLN]) for using zinc phosphide to control a variety of localized rodent (e.g., voles, tree squirrels, kangaroo and other rats, deer mice, muskrats, nutria) and jackrabbit pests. Brodifacoum and bromethalin are or have been used under emergency exemptions (FIFRA §18) to control introduced rats on U. S. islands in the Pacific Ocean. Twenty-three states have SLNs for chlorophacinone and/or diphacinone, mostly to control meadow voles (*M. pennsylvanicus*) and/or pine voles (*M. pinetorum*) in orchards or ground squirrels in rangeland or other uncultivated areas. Other limited uses include control of mongooses (*Herpestes auropunctatus*) in Hawaii, voles in small-grain crops in Washington, and a variety of other rodent pests and jack rabbits (*Lepus* spp.) in California. New Mexico uses cholecalciferol to control rock squirrels (*Spermophilus variegatus*).

Table 1. Commensal and Field Uses of Rodenticides in the United States (adapted from EPA 1998a,b)

Rodenticide	Date ai registered	Commensal uses	Field and other outdoor uses	mg ai/kg bait (ppm)
Second-generation anticoagulants				
Brodifacoum	1979	Rat and mouse control in and around buildings, transport vehicles, and inside sewers	Restricted-use applications for rat control on some oceanic islands (FIFRA §24c Special Local Needs [SLN] or FIFRA §18 emergency exemption)	50 25 (Anacapa Island, CA)
Difethialone	1995	Rat and mouse control in and around buildings in urban areas; limited to indoor use in non-urban areas	None	25
Bromadiolone	1980	Rat and mouse control in and around buildings, transport vehicles, and inside sewers in urban areas; limited to indoor use in non-urban areas	None	50
First-generation anticoagulants				
Chlorophacinone	1971	Rat and mouse control in and around buildings and inside sewers	Control of pocket gophers and moles in underground burrows; SLNs for control of pine and/or meadow voles in orchards (17 states), ground squirrels in rangeland and around burrows (8 states), jack rabbits (CA, OR), and a variety of other field rodents (e.g., deer mice, woodrats, muskrats) in CA	50 100 (some field uses) other[a]

Rodenticide	Date ai registered	Commensal uses	Field and other outdoor uses	mg ai/kg bait (ppm)
Diphacinone	1960	Rat and mouse control in and around buildings and inside sewers	Control of pocket gophers in underground burrows; SLNs for control of pine and/or meadow voles in orchards (16 states), ground squirrels in rangeland and around burrows (6 states), a variety of other field rodents (e.g., deer mice, woodrats, muskrats) and jack rabbits in CA, various field rodents in several other states, rat control on oceanic islands (HI, AK), and mongoose control (HI)	50 100 (some field uses) other[a,b]
Warfarin	1950	Rat and mouse control in and around buildings	Deer mouse and white-footed mouse control in and around buildings and in bait stations in other areas such as parks and woodlots	250 other[b]
Others (non-anticoagulants)				
Bromethalin	1984	Rat and mouse control in and around buildings, transport vehicles, and inside sewers	Restricted-use application for rat control on an oceanic island (emergency exemption)	100
Zinc phosphide	1940s	Rat and mouse control in and around buildings[a]	For control of a wide variety of field rodents (e.g., ground squirrels, prairie dogs, voles, rats, kangaroo rats, deer mice, moles, pocket gophers) in various sties, including rangeland, uncultivated areas, orchards, turf, forage, sugarcane, and other sites; 9 states also have SLNs for use against various rodents at local use sites	20,000 10,000 (CA only)
Cholecalciferol	1984	Rat and mouse control in and around buildings and inside transport vehicles	SLNs for control of rock squirrels (NM); also roof rats on an oceanic island (CA)	750

[a] chlorophacinone (0.2% ai), diphacinone (0.2% ai), and zinc phosphide (10% ai) tracking powders are registered for indoor use and inside burrows along building foundations; all are restricted-use products

[b] sodium salts of diphacinone and warfarin are registered for use in water baits for indoor use only

Adequate information quantifying usage of rodenticide baits is lacking. EPA obtains data on the amount of each product produced annually, and the Rodenticide Registrants Task Force (RRTF) provided some limited information on the pounds of active ingredient produced or imported in 1996 and 1997 for 4 of the 9 rodenticides (Kaukeinen et al. 2000). However, these data provide no information on when, where, or how the products are used and thus provide little relevant information for assessing exposure and risk. The RRTF data are difficult to interpret, because they lump containers and placement units, even though containers differ, often considerably, from placement units. A placement for commensal rodents is defined on product labels as 3 to 16 oz of bait for rats and 0.25 to 0.5 oz of bait for mice. In contrast, containers can hold anywhere from several to many individual rat or mouse placements. The problem with lumping these units together is illustrated in Table 2. Both brodifacoum and bromadiolone, for example, are formulated as 0.005% ai food baits solely for commensal rat and mouse control. The data for 1996 indicate that 395 lb ai of brodifacoum was formulated into more than 40 million "container/placement units" (i.e., 3 oz bait per container/placement unit), whereas 233 lb ai of bromadiolone was formulated into few more than 275,000 container/placement units (i.e., 271 oz bait per container/placement unit). Such differences also occur for 1997 and for chlorophacinone and diphacinone. Refining the exposure assessment would necessitate much better information for each rodenticide, including the amount of bait applied annually and seasonally; geographically by state or region; in field settings versus in and around buildings; in urban versus suburban and rural locales; indoor versus outdoor placements; applications for rats versus those for mice; use by the general public versus that by Certified Applicators; proportion of bait placements made in tamper-resistant bait stations; and, for chlorophacinone and diphacinone, use of 0.005% versus 0.01% ai baits.

Table 2. Amount of Bait and Number of "Container/Placement Units" For Four Anticoagulant Rodenticides in 1996 and 1997 (adapted from Kaukeinen et al. 2000). Information was not provided for difethialone, warfarin, or the non-anticoagulants.

Anticoagulant[a]	Year	lb ai[b]	oz bait[c]	no. containers/ placement units[b]	oz bait per container/ placement unit
Brodifacoum	1996	395	126,400,000	40,895,724	3
	1997	441	141,120,000	44,144,456	3
Bromadiolone	1996	233	74,560,000	275,376	271
	1997	164	52,480,000	294,706	178
Diphacinone	1996	486	155,520,000	1,551,161	100
	1997	608	194,560,000	2,860,419	68
Chlorophacinone	1996	1608	514,560,000	21,552	23,875
	1997	2677	856,640,000	18,360	46,658

[a] brodifacoum and bromadiolone are registered only for control of commensal rats and mice; diphacinone and chlorophacinone are registered for commensal rats and mice and are also used for control of field rodents in rangelands, orchards, and other settings

[b] data from Kaukeinen et al. 2000

[c] based on 0.005% ai food baits

Primary-hazards Data

Birds

Acute-oral and dietary toxicity: The available acute-oral and dietary toxicity data for birds are presented in Tables 3, 4, and 5. LC50 values for the northern bobwhite and mallard, required test species for EPA/OPP avian guideline studies, are used in calculating dietary RQs. The bobwhite or mallard LD50 also is used to calculate the amount of bait and number of rat-bait pellets that birds of various sizes need to eat to ingest a dose lethal to 50% of the individuals in the population. Some toxicity data also are available for other species for some rodenticides. Most of those values (e.g., Godfrey 1986) were determined using fewer test concentrations and fewer test animals per concentration than are required for EPA guideline studies. EFED considers these values as supplemental data that provide additional characterization of avian toxicity.

Table 3. Acute Oral and Dietary Toxicity of Second-generation Anticoagulants to Birds

Rodenticide/ Species	LD50, mg/kg (95% CI)	LC50, ppm (95% CI)	Reference
Brodifacoum			
Northern bobwhite		0.8 (0.1-4.7)	EPA 1998a
Mallard	0.26 (0-0.8)	2.0 (0.8-4.8)	EPA 1998a

[b] OPP/EFED Toxicity Database

[c] cited in Johnson and Fagerstone 1994

[d] values for cholecalciferol have been adjusted, based on the purity of test material (30% ai); reported values for the 30% ai test material are LD50 >2000 mg/kg; northern bobwhite LC50 = 1744 (1233-2516); and mallard LC50 = 3926 (2631-9890)

Feeding studies: Several studies are available that provide additional information for characterizing hazards of rodenticide baits fed to birds. Some of these provide useful comparative information among different rodenticides tested under the same test protocol. For example, Lund (1981) fed 0.005% ai brodifacoum, 0.005% ai bromadiolone, and 0.025% ai warfarin baits to adult leghorn chickens (*Gallus gallus*). Two anticoagulants (coumatetralyl and difenacoum) not registered in the U. S. also were tested. Four hens per anticoagulant were individually presented with a choice of bait or untreated chicken food for up to 15 days; survivors were observed for an additional 2 weeks. All 4 hens fed brodifacoum bait died within 6 to 12 days (Table 6). Bromadiolone bait resulted in the deaths of 2 of 4 hens. No deaths or signs of toxicity occurred in 3 hens that ate warfarin bait (1 other hen refused to eat bait).

Christopher et al. (1984) also examined the hazards of several anticoagulant baits to 3-week-old leghorn chickens. Brodifacoum bait (0.005% ai) was given to 4 groups (6 chicks per group) on alternate days for 1, 2, 3, or 4 feedings. Bromadiolone bait (0.005% ai) was presented to 3 groups (6 chicks per group) on alternate days for 1, 2, or 3 feedings. Warfarin bait (0.025% ai) was fed to 2 groups (6 chicks per group) for either 3 or 21 consecutive days. Results are comparable to those reported by Lund (1981). Twelve (50%) of the 24 birds fed brodifacoum bait died (Table 7), whereas all birds survived after feeding on bromadiolone bait (18 birds) or warfarin bait (12 birds).

Two other studies provide additional information help on the hazard of brodifacoum bait to birds. Ross et al. (1979a,b) exposed 10 northern bobwhites and 10 ring-necked pheasants (*Phasianus colchicus*) to 0.005% brodifacoum pellets for 14 days. Six bobwhite and 6 pheasants died after feeding ad lib. on a choice of pellets or untreated food. ICI Americas, Inc. (1981) also reported deaths of several pheasants exposed to 50 ppm brodifacoum pellets broadcast in a pen study.

Two laboratory studies provide supplemental data on the primary hazard of warfarin to birds. Crabtree and Robison (1952) maintained chukar (*Alectoris chukar*) on a diet of warfarin bait for 30 consecutive days with no deaths. Jones and Townsend (1978; cited in Townsend et al.1981) reported no mortality of Japanese quail (*Coturnix coturnix*) fed 8 mg ai/kg/day of warfarin for 14 days.

Johnson and Fagerstone (1994) reviewed primary hazard information for zinc phosphide. They indicate that some birds are repelled by zinc phosphide and others may regurgitate bait. Spotted doves (*Streptopelia chinensis*), for example, reportedly regurgitated treated seeds about 1 hour after ingestion (Hilton et al. 1972, Pank et al. 1972). However, some laughing doves (*Streptopelia senegalensis*) died about 2 hours after eating treated bait, even though they had regurgitated bait about 20 minutes after ingestion (Siegfried 1968). In another study, 14 of 15 red-winged blackbirds (*Agelaius phoeniceus*) died after feeding for 48 hours on a 1:1 mixture of treated (2% ai) and untreated cracked corn (Schafer et al. 1970).

Table 6. Adverse Effects of Five Anticoagulant Baits Fed to Adult Leghorn Chickens for up to 15 Days (adapted from Lund 1981)

	Avg. intake per bird[a]			
Anticoagulant	bait (g)	ai (mg/kg)	Mortality	Adverse effects
Brodifacoum (0.005% ai)	362 (252-443)	10.5 (7.1-15.0)	4/4	death from day 6
Bromadiolone (0.005% ai)	496 (329-684)	12 (5.9-16.9)	2/4	loss of appetite; hemorrhage from day 6
Warfarin (0.025% ai)	922 (584-1232)	149 (132-171)	0/3	none
Coumatetralyl[b] (0.03% ai)	594 (313-820)	107 (79-137)	2/4	loss of appetite from day 8; hemorrhage
Difenacoum[b] (0.005% ai)	611 (458-835)	19 (13.5-28.3)	2/4	loss of appetite; hemorrhage from day 5

[a] range is given in parenthesis

[b] coumatetralyl and difenacoum are not registered in the U. S.

Table 7. Adverse Effects of Three Anticoagulant Baits Fed to 3-week-old Leghorn Chickens for 1 to 21 Days (adapted from Christopher et al. 1984)

Anticoagulant	No. feedings[a]	Avg. bait intake (g)	mg ai/kg	Mortality	Adverse effects
Brodifacoum (0.005% ai)	1	15.5	11.0	1/6	1 death on day 4;1 bird sick on day 12 but recovered
	2	30.0	21.0	1/6	1 death on day 7;1 bird sick on day 6 but recovered
	3	42.8	28.9	5/6	mortality from days 7-16; 1 bird sick on day 5 (sporadic bleeding) had not recovered by end of test (day 21)
	4	43.8	20.9	5/6	mortality from days 5-15; 1 bird sick on day 4 (sporadic bleeding) had not recovered by end of test (day 21)
Bromadiolone (0.005% ai)	1	13.2	12.1	0/6	none
	2	29.5	22.1	0/6	1 bird sick on day 17 but recovered
	3	13.2	36.9	0/6	1 bird sick on day 16 did not recover by end of test (day 21)
Warfarin (0.025% ai)	3	49.4	183.7	0/6	none
	21	305.3	1092.2	0/6	bleeding in 1 bird on days 12-16 but survived

[a] brodifacoum and bromadiolone baits were offered ad lib. on alternate days; warfarin bait was fed ad lib. for either 3 or 21 consecutive days

Other studies indicate that zinc phosphide bait poses a hazard to some birds, although some species may be less susceptible than others. Janda and Bosseova (1970) reported deaths of gray partridges that consumed as few as 6 to 9 treated (2.5% ai) wheat kernels, and ring-necked pheasants died after consuming as few as 18 to 25 kernels. The California Department of Fish and Game (CDFA 1962) reports that about 260 to 310 treated zinc phosphide grains (1% ai) provides an LD50 dose for geese, and a 5-lb goose is capable of ingesting as many as 6400 kernels in one feeding (Keith and O'Neill unpubl.; cited in Johnson and Fagerstone 1994). Ramey et al. (1994) exposed ring-necked pheasants and California quail (*Callipepla californica*) to 2% zinc phosphide bait in 0.2-ha alfalfa enclosures. Based on necropsy results, 16 (62%) of 26 pheasants died from consuming bait. None of the 26 California quail died. Glahn and Lamper (1983) exposed 12 Canada geese (*Branta canadensis*) and 12 white-fronted geese (*Anser albifrons*) to 1% zinc phosphide bait applied in hay cover crops in California. The geese, held in portable enclosures that were moved daily, were allowed to feed for 4 days. Four (33%) Canada geese died. All white-fronted geese survived, which the authors attributed to their developing an aversion to bait after ingesting sublethal doses during the first 2 days of exposure.

Avian reproduction/sublethal effects: No guideline data are currently available for any of the rodenticides. OPP will be requiring avian reproduction tests with the mallard and northern bobwhite to fulfill this guideline requirement (40 CFR §158.490 Wildlife and Aquatic Organisms Data Requirements, Guideline Reference No. 71-4). EFED notes that there is a published abstract reporting the deaths of 2 turkey vulture (*Cathartes aura*) offspring that were fed brodifacoum-poisoned mice by their parents (Borst et al. 2000). The possibility exists that young animals may be more susceptible to rodenticide poisoning than are adults (see also the section on "*Mammalian reproduction/sublethal effects*"). EFED will assess the potential for adverse reproductive and chronic effects when the guideline studies become available.

Mammals

Acute-oral and dietary toxicity: The available acute-oral and dietary toxicity data for mammals are presented in Tables 8, 9, and 10. Laboratory-rat or mouse LD50 values are used to calculate the amount of formulated bait and number of bait pellets that nontarget mammals of various sizes need to eat to ingest a dose lethal to 50% of the individuals in the population. Data for other species provide additional characterization of mammalian toxicity and indicate that rodenticides are not selective for the target species. Some dietary data also are available for the laboratory rat for 5 of the anticoagulants, and these data are used to calculate dietary RQs. Additionally, as previously noted, all registered rodenticide products have been tested under Agency guideline requirements and proven efficacious in killing target species.

Warfarin toxicity values deserve special mention. LD50 values for the laboratory rat vary markedly among warfarin studies in the EPA/EFED toxicity database, ranging from 2.5 to 680 mg/kg. Jackson and Ashton (1992) cite values ranging from 14 to 186 mg/kg and Hone and Mulligan (1982; cited in Buckle 1994) values from 1.5 to 323 mg/kg. According to Meehan (1984; cited in Buckle 1994), the most reliable estimates now place the LD50 for the Norway rat as somewhere between 10 and 20 mg/kg. Discrepancies might exist due to difference in strain and gender of the rats and in the carrier used to administer the dose. Poché and Mach (2001) also suggest that the degradation rate of warfarin in the gastrointestinal tract (GIT) of rats probably depends on the variation of bacterial species present and their abundance.

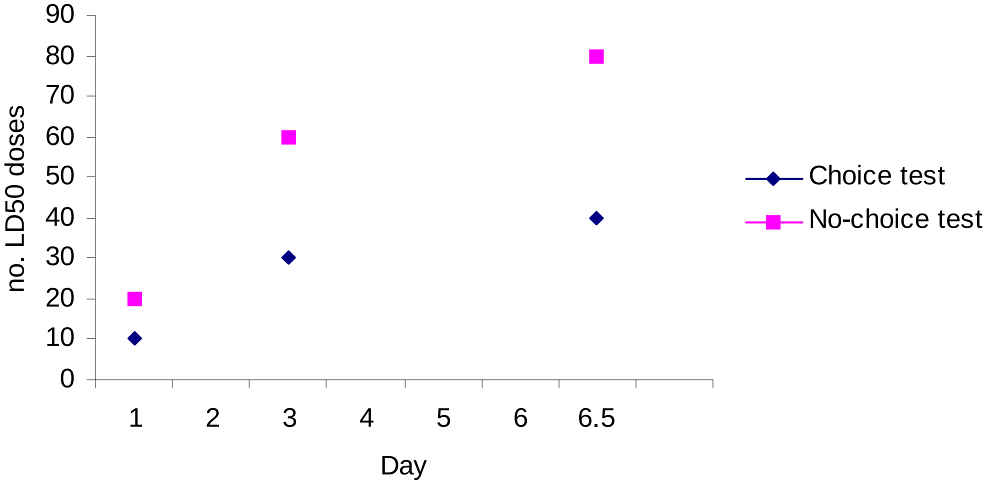
[e] the purity of the test material was not reported

Other toxicity information: ICI Americas, Inc. (1978b) provided some pertinent information on the approximate number of LD50 doses captive wild Norway rats consumed in their food (50 ppm brodifacoum bait) at various times until death, which averaged 6.5 days. The rats (sample size not specified) were either offered bait only or a choice of bait and untreated food. The rats in the no-choice group consumed an average of approximately 20 LD50 doses after 1 day of feeding and 80 LD50 doses by death (Figure 1). Rats offered a choice of bait or untreated food still consumed enough bait to have ingested an average of 40 LD50 doses at death.

Figure 1. Average number of LD50 doses consumed by captive wild Norway rats offered 50 ppm brodifacoum bait in no-choice (bait only) or choice (bait and untreated food) feeding tests (after ICI Americas, Inc. 1978b)



Some information is available to characterize the primary hazard of rodenticide bait to dogs and other nontarget species. Mackintosh et al. (1988) reported that some dogs have died after consuming as few as 8 brodifacoum (Talon) pellets. Lechevin and Poché (1988) indicate that 400 g of 0025% ai difethialone bait is the maximum amount tolerated by 10-kg dogs. In a study in which 2 dogs were exposed to a 0.025% ai warfarin bait, 1 died after feeding for 7 days on 12 g of bait daily and the other after feeding on 4.8 g of bait daily for 12 days (Prier and Derse 1962). Marsh (1985) calculated that an LD50 dose to a 10-lb dog could be provided with 23 g of brodifacoum bait, 85 g of diphacinone bait, 369 g of warfarin bait, and 1000 g of bromadiolone bait. Gunther et al. (1988) fed cholecalciferol bait to 4 dogs as a follow-up to an investigation of 2 dogs that died after consuming cholecalciferol bait. Two dogs were given a single meal containing approximately 540 g of bait (20 mg ai/kg) and 2 were given half that amount. All 4 dogs became lethargic, weak, and anorectic within 48 hours and all died 65 to 77 hours after treatment. These findings suggest that cholecalciferol bait may present more of a hazard to dogs than the LD50 of 88 mg ai/kg would suggest.

Dubock and Kaukeinen (1978) reported the following nontarget-hazards data for brodifacoum: "The deer mouse *Peromyscus maniculatus* completely succumbed (20/20 mortality) in a 1-day no-choice feeding test with 50 ppm brodifacoum (Marsh, unpublished)." and "100% mortality has been obtained against the ground squirrel *Spermophilus beecheyi* when offered 50 ppm brodifacoum bait no choice for 1, 2 or 3 days (Marsh, unpublished)."

Mammalian reproduction/sublethal effects: EFED typically utilizes the rat two-generation reproduction test to assess reproductive risks to mammals. This study (40 CFR §158.340 Toxicology Data Requirements, Guidelines Reference No. 83-4) is required by HED to support registration of pesticides with food uses or where use of the product is likely to result in human exposure over a significant portion of the human lifespan. This study is not currently available for any of the 9 rodenticides. HED also requires other subchronic/chronic studies, but most (e.g., dermal, inhalation, oncogenicity, neurotoxicity) provide measurement endpoints not relevant to assessing risk to nontarget mammals other than humans.

Some evidence exists that sublethal doses can have adverse effects. The Warfarin RED (EPA 1991a) notes that warfarin is a teratogen, and product labels are required to warn that "Exposure to warfarin during pregnancy should be avoided. Warfarin may cause harm to the fetus, including possible birth defects." The Rodenticide Cluster RED (EPA 1998a) reports developmental toxicity (e.g., vaginal bleeding, hypotonicity) in rats and rabbits exposed to bromadiolone at about two orders of magnitude less than the LD50 dose. In brodifacoum studies, internal hemorrhage and significantly prolonged prothrombin time of rabbits was reported for those dosed during gestation at about two orders of magnitude less than the LD50 dose. More recently, Munday and Thompson (2003) detected brodifacoum in two dog pups that died a few hours after birth. Of 13 pups from a single litter, eight were born dead or died within 48 hours of birth. Three puppies that died shortly after birth were necropsied. Two exhibited hemorrhage in the thoracic and peritoneal cavities, intestinal serosa, and meninges, and brodifacoum was detected in the liver of both puppies. The mother did not have any clinical signs of coagulopathy before or subsequent to whelping, and the authors suggest that fetuses may be more susceptible to brodifacoum than are adults.

Secondary-hazards Data

Birds

The available laboratory studies indicate that major differences occur among the rodenticides in their secondary hazard to birds, with brodifacoum displaying the greatest hazard and chlorophacinone and the non-anticoagulants the least. Thirty-one studies are cited in which raptors or avian scavengers were exposed to rodenticide in whole or ground carcasses, usually those of rats or mice, or in fortified meat. Second-generation anticoagulants were tested in 15 studies, first-generation-anticoagulants in 13 studies, and non-anticoagulants in 6 studies (note: some studies included more than one rodenticide group). Most prey animals were fed treated bait, although some were orally dosed. Most studies involved only 1 rodenticide but often more than 1 raptor or scavenger species was tested. Mortality is a measurement endpoint in all studies.

Some studies also report signs of toxicosis (e.g., bleeding, prolonged blood-coagulation time, abnormal behavior, regurgitation) in surviving test animals, and that information is included if reported. Although exposure scenarios, test species, and the number of test animals vary among the studies, collectively they provide sufficient information to characterize secondary hazards from short-term exposure. The studies are summarized and tabulated below. Two studies merit additional attention, because they test different rodenticides against the same test species under the same test conditions, and are discussed in more detail in the section "*Comparative anticoagulant studies*".

Second-generation anticoagulants: Some data are available for brodifacoum and bromadiolone but none for difethialone. Brodifacoum was tested in 11 studies involving 8 species. Of 149 individuals exposed to brodifacoum-poisoned prey, 63 (42%) individuals died (Table 11). Mortality occurred in 11 of 20 barn owls (*Tyto alba*), 6 of 6 red-tailed hawks (*Buteo jamaicensis*) and red-shouldered hawks (*Buteo lineatus*), 13 of 65 American kestrels (*Falco sparverius*), 1 of 4 Eurasian harriers (*Circus pygargus*), and 32 of 50 laughing gulls (*Larus atricilla*). No deaths occurred in 4 golden eagles (*Aquila chrysactos*) tested by Marsh and Howard (1978), but 3 bled externally. Some studies did not report whether signs of toxicosis were observed in surviving birds or not. In those studies that examined survivors for signs of toxicosis, such as external bleeding, internal hemorrhaging, and/or prolonged blood-coagulation time, about one-third of the survivors visually examined or necropsied exhibited symptoms of toxicity.

In contrast to brodifacoum, secondary exposure to bromadiolone caused the deaths of only 9 (8%) of 118 individuals in 5 studies (Table 12) that tested great-horned owls (*Bubo virginianus*), barn owls, red-tailed hawks, and Eurasian buzzards (*Buteo buteo*). Survivors also exhibited fewer signs of intoxication than did survivors in brodifacoum studies. Grolleau et al. (1989) reported bleeding in some of the 27 Eurasian buzzards that survived feeding on bromadiolone-poisoned voles for 3 days but reported no signs of intoxication in 59 survivors exposed for only 1 or 2 days. No signs of intoxication are reported by Poché (1988) or Mendenhall and Pank (1980) in 12 raptors (barn owls and red-tailed hawks) that survived feeding on bromadiolone-treated rodents for 3 to 10 days. Wyllie (1995) reported increased blood coagulation time in 6 barn owls fed bromadiolone-poisoned mice for 6 days, but coagulation times returned to normal within 10 days; all owls survived, and no evidence of hemorrhaging was seen.

[e] a second 1-day exposure period occurred 10 days after the first exposure

Only a few studies provide information on the residue level in the prey species offered to the secondary consumer. In those studies, the experimenter often manipulated residue levels to provide a known concentration or range of concentrations (e.g., ICI Americas, Inc. 1979a,b; LaVoie 1990; Gray et al. 1994). Additional information on whole-body residues in target species exposed to second-generation anticoagulants is provided in Table 13. Note that animals collected in the field were exposed to bait for an undetermined number of days. Some laboratory studies used bait concentrations different from that in baits registered in the U. S. and some exposed the primary consumer for only 1 day (e.g., Newton et al. 1990, Poché 1988).

Two residue studies indicate that the amount of whole-body residue in the target species is related to the amount of active ingredient in the bait. Kaukeinen (1982) provides mean tissue residue levels in voles exposed to brodifacoum bait in the laboratory. Separate groups of males and females were exposed for 4 days to 50 ppm bait or 10 ppm bait. Residues are 5.21 ppm and 2.17 ppm for males and females, respectively, exposed to 50 ppm bait but only 0.53 ppm and 0.40 ppm, respectively, for those exposed to 10 ppm bait. In field trials for vole control in orchards, Merson et al. (1984) collected voles 1 to 7 days after bait application. Two collections of voles exposed to 0.005% ai bait had mean whole-body residues of 2.07 ppm and 4.07 ppm, whereas those exposed to 0.001% ai bait had a mean residue level of 0.35 ppm.

First-generation anticoagulants: Mortality in studies with the 3 first-generation anticoagulants ranged from 0 to 9%. No mortality occurred in 8 chlorophacinone studies with 112 individuals from 9 species (Table 14). Birds tested included 28 carrion crows (*Corvus corone*), 20 Eurasian buzzards, 20 American kestrels, 20 black-billed magpies, 10 red-tailed hawks, 6 white storks (*Ciconia ciconia*), 4 tawny owls (*Strix aluco*), 2 barn owls, and 2 great horned owls. Some survivors showed signs of intoxication, mostly prolonged blood-coagulation time. About 9% mortality was recorded in 3 diphacinone studies with 34 individuals (Table 15). Test species were barn owls, great horned owls, saw-whet owls (*Aegolius acadicus*), golden eagles, and American crows (*Corvus brachyrhynchos*). Thirteen (42%) of the survivors displayed some signs of toxicity. In 4 warfarin studies, 2 (9%) of 23 individuals died (Table 16); no adverse signs were reported in the survivors. Whole-body residues in target species exposed to chlorophacinone, diphacinone, and warfarin are presented in Table 17.

Comparative anticoagulant studies: Some of the most meaningful studies for comparing hazards are those in which more than one rodenticide was tested by the same researchers under the same test conditions and with the same test species. Any adverse effects observed can more readily be attributed to differences among the rodenticides than to differences potentially confounded from utilizing different exposure scenarios or test species. The 2 studies summarized below indicate that brodifacoum has greater secondary toxicity to birds than do other anticoagulants tested, including bromadiolone, difenacoum and flocoumafen (both second-generation anticoagulants not registered in the U. S.), diphacinone, chlorophacinone, and fumarin (a first-generation compound no longer registered in the U.S.).

Mendenhall and Pank (1980) compared secondary hazards of 3 second-generation and 3 first-generation anticoagulants to barn owls. Six owls per rodenticide were exposed for either 1, 3, 6, or 10 days to rats fed with either brodifacoum (20 ppm bait), bromadiolone (50 ppm bait), or difenacoum (50 ppm). The exposed rats had been offered free choice of bait (5 to 13 g daily) or laboratory chow for 10 days; thus, none were forced to eat bait. An additional 2 owls per rodenticide were exposed for 10 days to rats fed with either diphacinone (50 ppm), chlorophacinone (50 ppm), or fumarin (250 ppm). Six of the 18 owls exposed to second-generation anticoagulants died, whereas none of the 6 owls offered first-generation anticoagulant-poisoned rats exhibited any signs of intoxication. Brodifacoum-fed rats accounted for 5 of the 6 owl deaths, even though the concentration of active ingredient in the bait fed to the rats is less than the 50 ppm in baits registered for rat and mouse control. The other mortality occurred in 1 of 2 owls exposed to bromadiolone-fed rats for 10 days. The amount of anticoagulant residue in the rats offered to the owls was not determined.

Wyllie (1995) and Newton et al. (1990) reported on toxic effects to barn owls fed mice exposed to brodifacoum (6 owls), bromadiolone (6 owls), or 2 other anticoagulants (difenacoum, flocoumafen). The mice had been fed bait (no choice) for a single day and allowed to die, which took 2 to 11 days. Dead mice were then offered to the owls in 3 phases, each phase separated by a recovery period lasting at least 75 days. In phase I, each owl was offered 3 mice for 1 day only. Surviving owls were offered 6 mice each during a 3-day period in phase II and 12 mice each during a 6-day period in phase III. Mortality, evidence of external bleeding, and delays in blood-coagulation times were monitored. Four of the 6 owls fed brodifacoum-exposed mice died within 6 to 17 days of phase I. Both survivors also survived feeding on poisoned mice in phases II and III, but both exhibited bleeding from the mouth, feet, and newly-grown feathers for up to 30 days, and blood-coagulation times did not reach normal until 16 to 78 days after treatment. In contrast, none of the owls exposed to bromadiolone-poisoned mice died or exhibited signs of hemorrhaging, and blood coagulation times returned to normal 4 to 6 days after treatment.

Others (non-anticoagulants): The few studies available for the non-anticoagulant rodenticides indicate few adverse secondary effects. Five studies are available for zinc phosphide (Table 18). Test birds included 2 great horned owls, 3 spotted eagle owls (*Bubo africanus*), 3 kestrels (*Falco tinnunculus*), 3 bald eagles (*Haliaeetus leucocephalus*), 3 black vultures (*Coragyps atratus*), 3 carrion crows, a magpie, and a jay. None of the 19 birds died, but signs of intoxication were noted in several individuals. Roosting-behavior irregularities were noted in 2 owls exposed to poisoned voles for 3 days (Bell and Dimmick 1975), and 3 bald eagles fed poisoned nutria (*Myocastor coypus*) for 4 to 5 weeks regurgitated some prey (Evans et al. 1966; cited in Johnson and Fagerstone 1994). In the only study available for cholecalciferol (Table 19), no adverse effects were observed in 2 turkey vultures and 1 red-tailed hawk exposed to rats fed for 1-day with 0.075% ai bait (Marsh and Koehler 1991). Each bird was offered 1 large or 2 small rats daily for 10 days. No hazard data are available for bromethalin.

Some whole-body residue data are available for zinc phosphide but none was found for cholecalciferol or bromethalin. Sterner et al. (1998) reported a mean whole-body residue of 0.42 (± 0.68) mg ai per vole for 6 voles each offered 5 oat-groat particles treated with 2% zinc phosphide. Mean particle weight was 23 mg, resulting in individual voles being offered only about 0.12 g of bait. In an earlier study (Sterner and Maudlin 1995), whole-body residues averaged 1.73 mg ai per vole (range = 0.31 to 4.95 mg ai) in voles offered bait ad libitum. Almost all zinc phosphide detected in carcasses apparently was in undigested bait in the GIT. Matscke and Andrews (1990) recovered only 8.9% of the amount of 2% ai bait ingested by voles, and 99.9% of that was in the GIT, especially the stomach. Only 0.1% of that recovered was detected in the kidneys, gall bladder, liver, and spleen combined, and none was detected in the lungs, heart, or in muscle. Tkadlec and Rychnovsky (1990) also reported that 99% of the zinc phosphide residue they detected in voles was in the GIT.

Table 18. Secondary Hazards of Zinc Phosphide to Birds in Laboratory Studies

Mammals

Laboratory tests indicate that the second-generation anticoagulants, as well as chlorophacinone and diphacinone, present a hazard to mammalian predators and scavengers. Thirty-three studies were found in which mammalian predators or scavengers were exposed to rodenticide in whole or ground carcasses, usually rats or mice, or in spiked meat. Second-generation anticoagulants were tested in 8 studies, first-generation-anticoagulants in 15 studies, and non-anticoagulants, mainly zinc phosphide, in 13 studies. Collectively, these studies provide sufficient information to characterize short-term secondary hazards for most of the rodenticides. Three studies in which different rodenticides were tested against the same test species under the same test conditions are discussed in more detail in the section *"Comparative anticoagulant studies*".

Second-generation anticoagulants: Mortality of 8 (42%) of 19 individuals (foxes, mustelids, domestic dogs) occurred in 4 brodifacoum studies (Table 20). Test subjects included 5 red foxes (*Vulpes vulpes*) and gray foxes (*Urocyon cinereoargenteus*), 4 mongooses (*Herpestes auropunctatus*), 4 weasels (*Mustela* sp.), and 6 domestic dogs. Signs of toxicity are reported for most survivors. In 4 bromadiolone studies (Table 21), 6 (23%) of 26 test animals died, including coyotes (*Canis latrans*), mongooses, and an ermine (*Mustela erminea*). Bleeding was observed in all 10 ermine that survived being fed 1 bromadiolone treated vole per day for 3 to 5 days, but not in 5 coyotes or 4 stone martens fed treated ground squirrels or mice for periods ranging from 1 to 5 days. No comparable secondary-hazard studies are available for difethialone. Goldade et al. (2001) estimated a chronic LD50 for European ferrets (*Mustela putorius furo*) fed difethialone-fortified dog food at various concentrations. The chronic LD50 of 760 mg ai/kg was estimated from cumulative daily food intake, difethialone concentration, and individual bird body weights, but only 2 ferrets were exposed to each test concentration and the duration of exposure was not specified.

First-generation anticoagulants: Laboratory studies indicate that chlorophacinone and diphacinone present a hazard to mammalian predators and scavengers. In 8 chlorophacinone studies, 32 (58%) of 55 individuals died, including 7 of 8 mongooses, 3 of 7 coyotes, 1 of 4 red foxes, 18 of 35 ferrets, and 3 of 4 weasels (Table 22). In 3 diphacinone studies, 19 (58%) of 33 test animals died after feeding on rodents fed diphacinone, liver tissue from owls fed diphacinone, or fortified meat. Species affected included mink (*Mustela vison*), mongooses, ermine, deer mice, rats, and dogs (Table 23). Warfarin appears to be less hazardous than other anticoagulants. In 7 studies, only 9 (9%) of 100 individuals died after eating warfarin-treated rodents (Table 24). Dead animals included 3 mink, 3 least weasels (*Mustela nivalis*), and 3 dogs.

[c] the 10 test animals included the 8 individuals from the first trial plus 2 additional untested individuals

Comparative anticoagulant studies: Marsh and Howard (1986) conducted a pen study to determine if ground squirrels fed either bromadiolone or chlorophacinone pose a secondary hazard to coyotes. The ground squirrels were fed either 0.01% ai bromadiolone bait or 0.01% ai chlorophacinone bait for 5 consecutive days. Each coyote (7 per rodenticide) was offered 1 dead ground squirrel per day for 5 days and observed for 30 days posttreatment. Three coyotes died after feeding on the dead ground squirrels previously fed chlorophacinone. All 7 coyotes fed dead ground squirrels previously fed bromadialone survived, although 2 consumed very little of their normal food rations for 8 to 16 days after treatment.

Pank and Hirata (1976) fed poisoned rats to mongooses to examine possible secondary hazards of anticoagulant rodenticides. The rats were fed for 5 days with baits that included 0.002% ai brodifacoum, 0.005% ai bromadiolone, 0.005% ai chlorophacinone, and 0.005% ai diphacinone. One rat per day was offered to mongooses for periods ranging from 1 to 10 days. Exposure to rats fed either chlorophacinone or diphacinone resulted in deaths of 7 of 8 mongooses exposed for 3 to 10 days. Three of four mongooses fed rats that were previously fed bromadiolone were killed, however only 1 mongoose death (of 4 tested) was attributed to brodifacoum. It is noteworthy that although baits registered for rat and mouse control are 50 ppm bromadiolone, the bait used to feed the rats in this study was only 20 ppm.

Evans and Ward (1967) demonstrated that feeding on nutria for several days or more can pose a hazard to minks and dogs when these nutria have been previously been fed diphacinone and warfarin. In this study the rodenticide exposed nutria, with skin, head, tail, feet, and intestines removed, were fed to 3 commercial mink and 3 mongrel dogs. All mink and dogs died within 5 to 17 days of the secondary exposure to diphacinone. The 3 mink exposed to warfarin died within 8 to 15 days. Two of the 3 dogs survived exposure to warfarin for 16 days, although both had bloody feces and one became lethargic.

Others (non-anticoagulants): Fewer secondary-hazard testing has been done with the non-anticoagulant rodenticides, but the available data indicate considerably less hazards than for the anticoagulants. Only 3 (4%) of 77 test animals (foxes, dogs, ferrets, weasels, domestic cats, mink, mongooses) died after feeding on rodents poisoned with zinc phosphide in 10 studies (Table 25). Some regurgitation of prey was reported in animals that died and in some survivors that consumed GI tracts of zinc phosphide-poisoned rodents (Evans 1965, Schitoskey 1975, Hill and Carpenter 1982, Tkadlec and Rychnovsky 1990). Some animals learned to avoid eating the GI tract. In 2 cholecalciferol studies, 18 dogs and 12 feral house cats consumed either poisoned ground rats or brushtail possums (*Trichosurus vulpecula*) for up to 5 days with no deaths, although some reversible signs of toxicosis were reported in the dogs (Table 26). In one study with bromethalin, 4 dogs survived with no observed adverse effects after feeding for 14 days on rats that were poisoned for 1 day (Table 27).

Potential Primary Risks

Birds

The amount of bait and number of rat-bait pellets (0.2 g each) that birds of various sizes need to eat in a single feeding to obtain a dose expected to be lethal to 50% of the individuals in the population (i.e., LD50 dose) are estimated from the acute oral toxicity for the northern bobwhite or mallard. Estimates of food-ingestion rates (g dry matter per day) are determined from allometric equations in Nagy (1987; cited in EPA 1993): 6.1 g for a 25-g passerine, 9.6 g for a 100-g non-passerine, and 53.9 g for a 1000-g non-passerine. A 25-g passerine can potentially ingest an LD50 dose by consuming 0.02 g zinc phosphide bait (<1 pellet), 0.13 g brodifacoum bait (<1 pellet), 0.26 g difethialone bait (<2 pellets), or 1.2 g (6 pellets) of bromethalin bait (Table 28). Larger non-passerines need to consume more pellets to obtain an LD50 dose but could potentially do so. In contrast, 25- to 1000-g birds would need to eat 100 or more pellets to ingest an LD50 dose of bromadiolone, chlorophacinone, diphacinone, warfarin, or cholecalciferol.

Most of the rodenticide baits, but especially brodifacoum, difethialone, and zinc phosphide, exceed the Agency's LOC for avian dietary risk (Table 29). The Agency presumes potential acute risk when the dietary RQ equals or exceeds 0.5 for non-endangered species and 0.1 for endangered species. Brodifacoum, difethialone, and zinc phosphide exceed the LOC for non-endangered species by 86- to 126-fold for the northern bobwhite and 14- to 50-fold for the mallard. The exceedances are even higher for endangered species.

Table 28. Comparative Risk to Birds From a Single Feeding of Rodenticide, Based on the Amount of Bait Needed to Ingest an LD50 Dose (i.e., a dose lethal to 50% of the individuals in a population)

			25-g passerine			100-g non-passerine			1000-g non-passerine		
Rodenticide	mg ai/kg in bait	LD50[a] (mg ai/kg)	bait (g)	% of daily food intake[b]	no. bait pellets[c]	bait (g)	% of daily food intake	no. bait pellets	bait (g)	% of daily food intake	no. bait pellets
Second-generation anticoagulants

		mallard	620	0.2
Zinc phosphide	20,000	northern bobwhite	469	43
		mallard	2885	7
Cholecalciferol	750	northern bobwhite	528	1.4
		mallard	1190	0.6

[a] LC50 values used to calculate the dietary RQs are from dietary toxicity studies required by the Agency to support pesticide registration (see Tables 3, 4, and 5)

[b] RQ = ppm ai in bait/LC50; RQs are not calculated when the LC_{50} value categorizes the active ingredient as practically nontoxic (i.e., LC50 >5000 ppm) to the test species

Based on the comparative analysis model, zinc phosphide, brodifacoum, and difethialone stand out as the rodenticides posing the greatest potential primary risk to birds. This result is based on two measures of effect: mean dietary RQ (ppm bait/LC50) and the number of bait pellets needed for a 100-g bird to ingest an LD50 dose in a single feeding. In order to correctly calculate the weighted averages, the inverse of the number of bait pellets needed for a 100-g bird to ingest an LD50 dose in a single feeding was calculated and used in the comparative analysis model. The sum of the weighted average values for all the rodenticides is tabulated in the 'Summary values' column in Table 30 and also is depicted in Figure 2. Brodifacoum has higher summary risk values than difethialone for both measures of effect. The mean dietary RQ appears to be the most significant measure of effect leading to the conclusion that brodifacoum poses greater potential risk to birds than either difethialone or zinc phosphide and that difethialone poses greater potential risk to birds than does zinc phosphide.

Table 30. Comparative Analysis Model Results for Primary Risk to Birds

Rodenticide	mg ai/kg bait	Measure-of-effect values		Summary values
		Mean dietary RQ[a]	Inverse of the LD50 dose for a 100-g bird (no. bait pellets)[b]	
Brodifacoum	50	44.00	0.38	5.58
Bromadiolone	50	0.85	0.00	0.10
Bromethalin	100	0.35	0.04	0.10

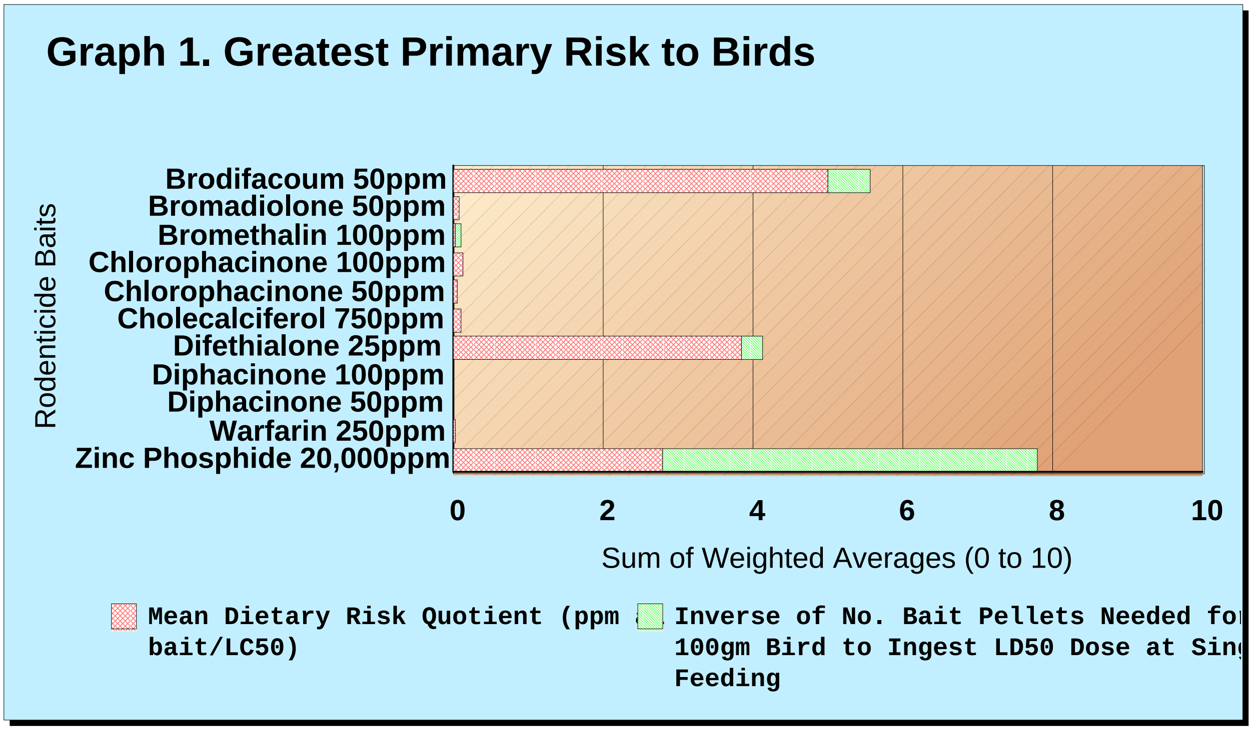
[b] from Table 28

Figure 2. Comparative Analysis Model Summary Values For Primary Risk to Birds



Primary risk to birds also is analyzed by an alternative approach, using an HD_5(50%) reference value to calculate the amount of bait needed to provide an LD50 dose to a 100-g bird instead of the LD50 values for bobwhite quail or mallard ducks. The HD_5(50%) is the 5% tail of the avian LD50 toxicity distribution calculated with 50% probability of overestimation (Mineau et al.2001). The authors believe that the *"approach of using reference values based on species specific extrapolation factors represents the most unbiased attempt to date to compare the toxicity of pesticides for which many data points are available with those about which we know very little."* Utilizing the HD_5(50%) reference value, rather than the LD50, does not change the rankings (see Attachment C for more details, including reference values for the rodenticides and a graphical comparison of the summary measures of effect for each of the 2 approaches).

Findings from experimental studies conducted in field or other outdoor settings, along with information obtained during operational programs, provide useful data linking exposure to adverse effects in birds. Zinc phosphide, chlorophacinone, and diphacinone are registered for field and other outdoor uses, and brodifacoum has been used to control introduced rats on some U. S. oceanic islands. Such uses often allow broadcast or other unprotected applications (e.g., spot-baiting) that exposes bait to birds that might be attracted to grain pellets or treated grains (e.g., corn, wheat, oats).

Howald et al. (1999) reported nontarget effects to birds during a brodifacoum rat-control program on Langara Island, Canada. Thirteen common ravens (*Corvus corax*) were found dead 12 to 47 days after baiting began, and all had brodifacoum residue (0.985 to 2.522 ppm) in their liver. Remains of 7 other ravens also were found but not analyzed. At least 8 bait stations were raided by ravens, which either reached into the stations and pulled out bait blocks or tipped the stations to roll out the bait, even though the stations were secured. Some of the ravens also fed on poisoned rats. Brodifacoum also was detected in a pooled sample of 3 northwestern crows (*C. caurinus*) collected 12 days after the start of baiting.

Brodifacoum also was detected in song sparrows (*Melospiza melodia*) collected by shotgun on Langara Island (Howald 1997). Residue levels of 0.643 and 0.567 ppm were detected in 2 of 4 pooled liver samples (2 to 3 individuals per sample) and 0.058 ppm in 1 pooled sample (4 individuals) analyzed for whole-body residue. It is not known how the sparrows were exposed or whether any died. They may have consumed bait crumbs found scattered around bait stations and along rat runways but also might have eaten invertebrates that fed on bait. Howald (1997) also found that snails (*Vespericola* sp., *Haplotrema* sp.) and banana slugs (*Ariolimax* sp.) commonly fed on brodifacoum bait and may pose a risk to birds and nontarget mammals that consume them.

Godfrey (1985) cited an incident at an aviary where several birds (avocets, pittas, plovers, finches, thrushes, warblers, crakes, honey creepers) died after being exposed to brodifacoum. Brodifacoum concentrations of 0.081 to 1.69 ppm were reported in tissues of dead birds. Because bait was applied in bait stations, it was assumed that the birds were exposed by feeding on pavement ants and cockroaches that had eaten bait.

Brodifacoum baits (20 ppm or 50 ppm) are used for field control of rats and brushtail possums in New Zealand, and much useful information on nontarget risks has been reported. However, because of increased concerns about nontarget mortality and movement of brodifacoum through the food chain, its use is being reviewed and curtailed in many areas in New Zealand (Eason and Murphy 2001). The following studies provide further information on primary risks to birds, based on mortality reported during field studies or operational control programs.

Eason and Spurr (1995) reviewed the impacts of brodifacoum baiting on nontarget birds during baiting programs in New Zealand, where bait is applied in bait stations (50 ppm cereal-based wax blocks) or aerially broadcast (20 ppm pellets) in a single application. They report mortality of a wide range of bird species, including 33 indigenous species or subspecies and 8 introduced species or subspecies, and presume most resulted from primary exposure. Populations of indigenous rails (weka, *Gallirallus australus*; pukeko, *Porphyrio porphyrio*) monitored during rodenticide baiting operations were severely reduced: "For example, the entire population of western weka on Tawhitinui island were exterminated by consumption of Talon® 50WB intended for ship rats, which they obtained by reaching into bait stations, by eating baits dropped by rats, and by eating dead or dying rats (Taylor 1984)." On another island, 80 to 90% of the Stewart Island weka population was killed by baits applied for Norway rats. Aerial application of 0.002% bait on two other islands reduced a weka population by about 98% and a pukeka population by >90%. Numbers of quail, blackbirds, sparrows, and myna were markedly reduced on another island. Some other species suffered no apparent adverse effects.

Dowding et al. (1999) found numerous dead birds after an aerial baiting operation to eradicate rats and mice and reduce rabbit numbers on Motuihe Island, New Zealand. Brodifacoum bait (20 ppm) was applied twice, with 9 days between applications. Nontarget species were monitored, including pukeka (3 groups of 98 birds), a flock of 52 paradise shelduck (*Tadorna variegata*), 8 New Zealand dotterels (*Charadrius obscurus*), and 14 variable oystercatchers (*Haematopus unicolor*). There was no evidence that dotterels or oystercatchers were adversely affected, but mortality of pukeko and shelduck was 49% and 60%, respectively. Birds of 10 species were found dead. The liver from each of 29 dead birds of 10 species was analyzed. All livers contained brodifacoum residue, with mean levels per species ranging from 0.56 to 1.43 ppm. Chaffinch (*Fringilla coelebs*), North Island robin (*Persica australis longipes*), North Island weka, and North Island saddleback (*Philesturnus carunculatus rufusater*) also were found dead after a brodifacoum baiting on Mokoia Island, New Zealand (Stephenson et al.1999).

Eason and Spurr (1995) report that invertebrates have been observed eating brodifacoum bait, and residues were detected in beetles collected in bait stations in New Zealand. Invertebrates have different blood-clotting mechanisms than vertebrates and may not be affected by anticoagulants, but insectivorous animals feeding on the contaminated invertebrates might be at risk. Robertson et al. (1999) monitored brown kiwis (*Apteryx mantelli*) potentially at risk from brodifacoum applications in bait stations placed for possum control. Although there was no evidence that adult kiwi died as a result of the applications, including 55 that were radio-tagged, brodifacoum was detected at levels of 0.01 to 0.18 ppm in 3 of 4 chicks found dead from unknown causes. The authors speculated that the chicks may have obtained bait or may have eaten invertebrates that ingested bait. The death of an endangered Seychelles magpie-robin (*Copsychus sechellarum*) on Fregate Island, Seychelles, was likely due to its feeding on insects that had taken brodifacoum baits from bait stations (Thorsen et al. 2000). Loss of bait, attributed mostly to consumption by millipedes, crabs, and skinks, averaged 17% per night.

Hegdal (1985) conducted a study in Washington to examine risks to game birds from a 0.005% ai diphacinone bait applied for vole control in orchards. Most orchards were treated twice, with 20 to 30 days between treatments, at an average rate of 12.9 kg/ha (11.5 lb/acre). Telemetry was used to monitor the fate of 52 ring-necked pheasants, 18 California quail, and 30 chukar potentially exposed to the bait. About half of the quail and all chukar were pen-raised and had been released into the orchards. Dead game birds and other animals found were necropsied and any available tissue collected for residue analysis. Eight of 30 pheasants, 9 of 15 quail, and 1 of 10 chukar collected by the researchers or shot by hunters contained diphacinone residue in the liver. Bait made up as much as 90% of crop contents of some birds. No residue was detected in 4 passerines collected 31 to 73 days after treatment. The author concluded that risk to game birds in orchards appeared to be low but emphasized that substantial quantities of bait were eaten and longer-term behavioral and physiological effects, such as susceptibility to predation, need to be considered along with direct mortality in order to evaluate potential hazards from exposure.

Some information on potential nontarget risks was gained during field studies conducted to assess the efficacy of 0.01% ai and 0.005% ai diphacinone and chlorophacinone baits against California ground squirrels inhabiting rangeland (Baroch 1994 a,b; 1996a,b). For each of these rodenticides, trials included separate spot-baiting applications with 0.01% ai and 0.005% ai grain baits and a trial in which 0.005% ai grain bait was only available in bait stations. Searches for nontarget carcasses were made on and around treated plots after baiting. One dead dove and 2 dead roadrunners (*Geococcyx californicus*) were found on treatment plots, but there was no evidence that these birds had eaten any bait.

Hegdal and Gatz (1977) evaluated risks to nontarget wildlife from zinc phosphide bait (2% ai) broadcast by ground or air at rates of 5 to 10 lb per acre for vole control in Michigan orchards. Carcass searches were made across 672 of 950 treated acres in the 2 weeks after treatment. Bird carcasses recovered included 1 blue jay (*Cyanocitta cristata*) and 1 of 5 radio-equipped pheasants. Northern bobwhite were observed, and some were seen feeding on bait, but no carcasses were found.

Ramey et al. (1998) examined risk to radio-collared ring-necked pheasants from zinc phosphide baiting in alfalfa fields in California. Pheasants were rarely found in fields when bait was applied after the alfalfa was cut. The pheasants preferred other habitats at this time, and none died as a result of the baiting. Results were somewhat confounded by the use of some pen-reared pheasants, most of which were quickly taken by predators.

Johnson and Fagerstone (1994) reviewed a number of field studies conducted to evaluate primary effects of zinc phosphide on nontarget wildlife for the following uses: prairie dogs, ground squirrels, and jackrabbits on rangeland; California ground squirrels and rats on ditch banks; voles and rats in orchards; and rats in sugarcane. They also note that some information on nontarget hazards has also been gathered for use against voles in alfalfa and muskrats and nutria in wetlands. They concluded: "Although field studies to determine effects of zinc phosphide on nontarget wildlife have generally found no significant effects, under certain circumstances operational zinc phosphide applications have resulted in mortality of nontarget wildlife."

Quy et al. (1995) observed small song birds, especially chaffinches, that had difficulty flying and appeared to be ill during a rat-control operation with calciferol bait in the United Kingdom. A number of dead birds were found; all had abnormally high calcium deposits in their kidneys, suggesting calciferol toxicosis.

Nontarget mammals

The amount of bait and number of rat-bait pellets that nontarget mammals of various sizes need to eat in a single feeding to obtain an LD50 dose (i.e., the dose expected to be lethal to 50% of the individuals in the population) is estimated from the acute oral toxicity for the laboratory rat. Estimates of food-ingestion rates (g dry matter per day) are determined from allometric equations in Nagy (1987; cited in EPA 1993): 3.8 g for a 25-g rodent, 8.3 g for a 100-g rodent, and 68.7 g for a 1000-g mammal. A 25-g rodent can potentially ingest an LD50 dose by consuming less than 1 g (~5 pellets) of most baits, and a single pellet of zinc phosphide or brodifacoum can provide this dose (Table 31). Larger mammals also are potentially at risk if they eat baits of most of these rodenticides. For warfarin, there is some uncertainty that a single feeding would be lethal to most individuals, because warfarin is reported to require multiple feedings over a period of a few days to be efficacious (Papworth 1958, Jackson and Ashton 1992, Timm 1994).

Dietary RQs are calculated for brodifacoum, bromadiolone, and the 3 first-generation anticoagulants (Table 32). RQs cannot be determined for difethialone and the 3 non-anticoagulants, because dietary data are not available. The RQs exceed the LOC 48- to 188-fold for non-endangered mammals and 240- to 943-fold for endangered mammals. This indicates a significant risk to nontarget mammals that feed on any of these baits.

Based on the comparative analysis model, zinc phosphide is ranked as the rodenticide posing the greatest potential primary risk to nontarget mammals, with brodifacoum ranked a distant second, and warfarin and bromadiolone an even more distant third and fourth. The results are based on a single measure of effect: the number of bait pellets needed for a 100-g mammal to ingest an LD50 dose in a single feeding. In order to correctly calculate the weighted averages, the inverse of the number of bait pellets needed for a 100-g mammal to ingest an LD50 dose in a single feeding was calculated and used in the comparative analysis model. The sum of the weighted average values for all the rodenticides is tabulated in the ‘Summary values' column in Table 33 and presented graphically in Figure 3.

Table 31. Comparative Risk to Mammals From a Single Feeding of Rodenticide, Based on the Amount of Bait Needed to Ingest an LD50 Dose (i.e., a dose lethal to 50% of the individuals in a population)

			25-g rodent			100-g rodent			1000-g mammal		
Rodenticide	mg ai/kg in bait	LD50[a] (mg ai/kg)	bait (g)	% of daily food intake[b]	no. bait pellets[c]	bait (g)	% of daily food intake	no. bait pellets	bait (g)	% of daily food intake	no. bait pellets
Second-generation anticoagulants											
Brodifacoum	50	0.4	0.2	5.2	1	0.8	9.6	4	8	11.6	40
Difethialone	25	0.55	0.56	14.7	2.8	2.2	26.5	11	22	32	110
Bromadiolone	50	0.7	0.35	9.2	1.8	1.4	16.2	7	14	20.4	70
First-generation anticoagulants											
Chlorophacinone	50	6.2	3.1	81.6	15.5	12.4	>100	62	124	>100	620
Chlorophacinone	100	6.2	1.6	42	8	6.2	74.7	31	62	90.2	310
Diphacinone	50	2.3	1.2	31.6	6	4.6	55.4	23	46	67	230
Diphacinone	100	2.3	0.6	15.8	3	2.3	27.7	11.5	23	33.5	115
Warfarin	250	3	0.3	7.9	1.5	1.2	14.5	6	12	17.5	60
Others (non-anticoagulants)											
Bromethalin	100	9.9	2.5	65.8	12.5	9.9	119	49.5	99	>100	495
Zinc phosphide	20,000	21	0.03	0.7	0.13	0.1	1.2	0.5	1	1.5	5
Cholecalciferol	750	42	1.4	36.8	7	5.6	67.5	28	56	81.5	280

[a] the LD50 values used in the calculations are from laboratory rat or mouse acute-oral toxicity studies required by the Agency to support pesticide registration (see Tables 6, 7, and 8); the tabulated value is provided as an average if the LD50 differed between male and female

[b] food ingestion rates (g dry matter per day) are based on the allometric equations of Nagy 1987 (cited in EPA 1993): 3.8 g for a 25-g rodent, 8.3 g for a 100-g rodent, and 68.7 g for a 1000-g mammal

[c] assuming a bait pellet weighs 0.2 g (information provided by Syngenta Crop Protection, Inc., Greensboro, NC)

Table 32. Mammalian Dietary Risk Quotients. RQs ≥0.1 (endangered species) or ≥0.5 (non-endangered species) Exceed the Agency's Level of Concern for Acute Risk to Mammals.

Rodenticide	mg ai/kg in bait	Test species	LC50[a] (ppm)	Dietary RQ[b]
Second-generation anticoagulants				
Brodifacoum	50	laboratory rat	0.53	94.3
Bromadiolone	50	laboratory rat	0.92	54.3
First-generation anticoagulants				
Chlorophacinone	50	laboratory rat	1.14	43.8
Chlorophacinone	100	laboratory rat	1.14	87.7
Diphacinone	50	laboratory rat	2.08	24.0
Diphacinone	100	laboratory rat	2.08	48.1
Warfarin	250	laboratory rat	4.41	56.7

[a] LC50 values used to calculate the dietary RQs are from dietary toxicity studies conducted by the Agency's former Toxicology Section (see Tables 6 and 7); mammalian dietary data are not available for difethialone, bromethalin, zinc phosphide, and cholecalciferol

[b] RQ = ppm ai in bait/LC50

Table 33. Comparative Analysis Model Results for Primary Risk to Nontarget Mammals

Rodenticide	mg ai/kg bait	Inverse of the LD50 dose for a 100-g rodent (no. bait pellets)[a]	Summary value
Brodifacoum	50	0.25	1.25
Bromadiolone	50	0.14	0.71
Bromethalin	100	0.02	0.10
Chlorophacinone	100	0.03	0.16
Chlorophacinone	50	0.02	0.08
Cholecalciferol	750	0.04	0.18
Difethialone	25	0.09	0.45
Diphacinone	100	0.09	0.43
Diphacinone	50	0.04	0.22
Warfarin	250	0.17	0.83
Zinc Phosphide	20,000	2.00	10.00

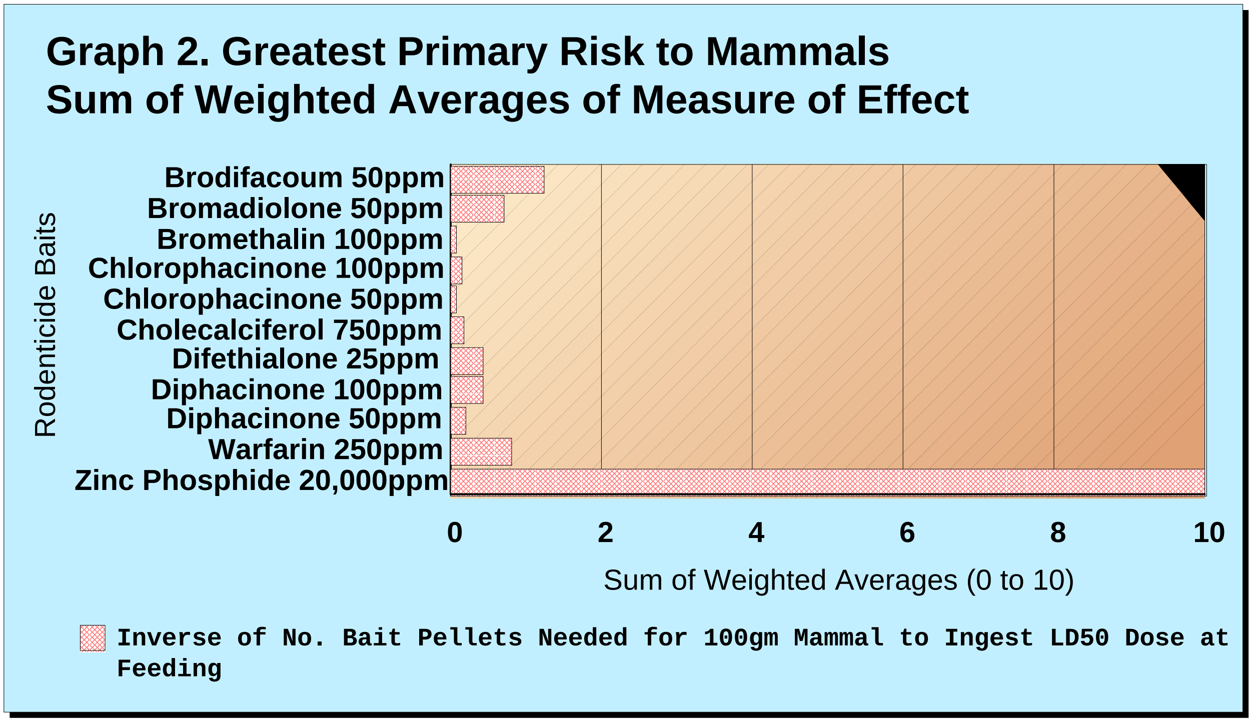
Figure 3. Comparative Analysis Model Summary Values For Primary Risk to Nontarget Mammals



The little information available on primary risk to mammals in the field has mostly come from animals found dead or moribund on treatment plots during efficacy trials and from an operational control program on a Canadian island. Howald (1997) reported that dusky shrews (*Sorex monticolus*) entered bait stations and fed on brodifacoum bait during a rat-control program on a Canadian island. By day 20 of baiting, shrews had eaten bait in 80% of the 42 rat bait stations. The shrew population declined sharply but rebounded to about half the prebaiting level after baiting stopped in 1994; however, shrew numbers declined further when baiting resumed in 1995. The long-term impact of baiting on the shrew population is unclear. No difference in population size was found pre- and post-baiting on a larger, adjacent island.

Some information on nontarget risks was gained during studies conducted to assess the efficacy of 0.01% ai and 0.005% ai chlorophacinone and diphacinone baits against California ground squirrels inhabiting rangeland. Baroch (1996a,b) applied chlorophacinone bait by spot-baiting or in bait stations, and treatment plots were searched periodically for target and nontarget carcasses . Thirty-six nontarget deer mice, San Joaquin pocket mice (*Perognathus inornatus*), and woodrats were found dead; based on the presence of blue dye incorporated into the bait and/or signs of internal or external hemorrhaging, mortality of 31 (86%) mice was attributed to the baiting. Four dead desert cottontails (*Sylvilagus auduboni*) and 2 dead Botta's pocket gophers (*Thomomys* *bottae*) also were collected, but there was no evidence that these had been exposed to bait. In another study designed to assess the efficacy of chlorophacinone and diphacinone baits, some small mammals, especially kangaroo rats (*Dipodomys* spp.), were found dead on treated plots (Salmon et al. 2002). Collectively, these studies indicate that some small nontarget mammals will be killed when these baits are applied for controlling ground squirrels.

Comparative Toxicokinetics: Absorption, Metabolism and Excretion of Anticoagulants

Considerable differences exist in absorption, metabolism and excretion of the anticoagulants, which may have important consequences for both primary and secondary risk. A compound that is rapidly metabolized or excreted from a primary consumer may result in a lesser risk than one that bioaccumulates with repeated sublethal exposure, even if repeated exposure occurs weeks or even months after initial exposure (Eason and Murphy 2000). Those compounds more rapidly cleared from the body are less likely to pose such long-term risk. The available information indicates that the second-generation anticoagulants are much more persistent in animal tissue than are the first-generation anticoagulants. Data also suggest that brodifacoum may be more persistent than either difethialone or bromadiolone. Few data exist for the non-anticoagulants but, based on lack of toxicity in secondary tests, apparently they are not retained in toxicologically significant amounts in animal tissues.

Most of the available information is from studies that examined elimination and retention following a single, sublethal oral dose of anticoagulant. In a baiting situation, however, rats or mice will not die for several days or more after ingesting a lethal dose and may continue consuming bait. A wild Norway rat may ingest as many as 80 brodifacoum LD50 doses if feeding only on bait and as many as 40 LD50 doses if offered a choice of bait or untreated food (ICI Americas, Inc. 1978b). In a situation of repeat exposure for several days or more, anticoagulant may circulate in the blood at higher levels and for a longer time than suggested by studies in which only a single, sublethal dose was administered (Belleville 1981).

Elimination of anticoagulants from the body is sometimes described as rapid (e.g., Poché 1986, Kaukeinen et al. 2000). However, such characterizations usually refer to the rapid excretion of unbound or unabsorbed material being excreted principally in feces during the first few days after administration. Alternatively, it may refer to the clearance from the blood as compared with tissue retention. Rather than concentrating on the amount of anticoagulant excreted, risk assessments should focus on the material retained in the body after single and multiple exposures. The studies summarized below indicate the differences among these compounds and their potential to bioaccumulate with repeat exposure.

Second-generation anticoagulants

Second-generation compounds are not readily metabolized, and the major route of excretion of unbound compound is through the feces. After absorption, high concentrations circulate in the blood and are rapidly established in the liver and other tissues. Half-lives in the blood of rats are 1.0 to 1.4 days for bromadiolone and 6.5 days for brodifacoum (Table 34). Elimination from liver is much slower and biphasic, with a very prolonged terminal phase. It is apparent from the studies discussed below that a proportion of any ingested dose of a second-generation anticoagulant bound in the liver, kidney, or pancreas remains in a stable form for some time and is only very slowly excreted.

Hawkins et al. (1991) administered brodifacoum and bromadiolone to rats in a single oral dose of 0.2 mg ai/kg. Elimination was biphasic, with half-lives of 63 days for brodifacoum and 17 days for bromadiolone in the initial 28 days and 282 and 318 days, respectively, in the terminal phase. These differences are not statistically significant, but mean liver concentrations of brodifacoum were significantly higher for brodifacoum throughout the study (Table 35).

Bratt and Hudson (1979) found that radiolabeled brodifacoum was rapidly and almost completely absorbed when administered to rats in a single oral dose (0.25 mg ai/kg). After 10 days, about 11 to 14% had been eliminated in urine and feces, but 74.6% of the dose was still retained in body tissues. Almost half the dose administered was detected in the carcass and skin, with lesser amounts in the liver (22.8%), pancreas (2.3%), kidney (0.8%), spleen (0.2%), and heart (0.1%). The estimated half-life of brodifacoum in rat tissues was estimated to be 150 to 200 days.

Batten and Bratt (1987) orally dosed male rats with a single dose of radiolabeled brodifacoum at doses of either 0.02. 0.15, or 0.35 mg ai/kg. The highest concentration of radioactivity in the liver was found 1 day after dosing, but 21 to 34% of the dose was still detected after 13 weeks and >11% after 104 weeks (Table 36). The elimination half-life for the 2 lowest doses was 350 days. For rats dosed at 0.35 mg ai/kg, a near-lethal dose (LD50 = 0.39 to 0.56 mg ai/kg), elimination from the liver was biphasic and consisted of a rapid phase (days 1 to 4) in which the half-life was approximately 4 days and a slower phase (days 28 to 84) in which the half-life was 128 days. Two rats dosed at that level died during the study. Signs of brodifacoum toxicosis were observed in some survivors. Some dosed rats also had gained less body-weight and displayed signs of internal hemorrhage when dissected.

Table 34. Persistence of Second-generation Anticoagulants in Blood and Liver

Anticoagulant	Species	Dose (mg ai/kg)	No. doses	Blood $t_{1/2}$[a] (days)	Liver retention[a,b] (days)	Reference
Brodifacoum	rat	0.02 or 0.15	1		350[c] ($t_{1/2}$)	Batten and Bratt 1990
		0.35	1		128[d] ($t_{1/2}$)	
Brodifacoum	rat	0.2	1		282 ($t_{1/2}$)	Hawkins et al. 1991
Brodifacoum	rat	0.25	1		150-200 ($t_{1/2}$)	Bratt and Hudson 1979
Brodifacoum	rat	0.06	4 (at weekly intervals)		136 ($t_{1/2}$)	Belleville 1991
Brodifacoum	rat	0.35	1		130 ($t_{1/2}$)	Parmar et al. 1987
Brodifacoum	rat			6.5	>80	Bachmann and Sullivan 1983[e]
Brodifacoum	possum	0.1	1	20-30	>252	Eason et al. 1996
Brodifacoum	rabbit			2.5		Breckenridge et al. 1985[e]
Brodifacoum	sheep	0.2 or 2.0	1		>128	Laas et al. 1985
Brodifacoum	dog			6		Woody et al. 1992[e]
Brodifacoum	dog			0.9-4.7		Robben et al. 1998[e]
Brodifacoum	human			0.7-1.5		Weitzel et al. 1990[e]
Difethialone	rat	0.5	1	2.3	126 ($t_{1/2}$) (175%, 98&)	Belleville 1986
Difethialone	rat	0.06	4 (at weekly intervals)		74 ($t_{1/2}$)	Belleville 1991
Difethialone	dog			2.2-3.2		Robben et al. 1998[e]

Anticoagulant	Species	Dose (mg ai/kg)	No. doses	Blood $t_{1/2}$[a] (days)	Liver retention[a,b] (days)	Reference
Bromadiolone	rat	0.2	1		318 ($t_{1/2}$)	Hawkins et al. 1991
Bromadiolone	rat	0.93	1	1.0-1.1	170 ($t_{1/2}$)	Parmar et al. 1987
Bromadiolone	rat	0.8 3.0	1 1	1.1 2.4		Kamil 1987[e]
Bromadiolone	sheep	2.0	1		256	Nelson and Hickling 1994[e]

[a] $t_{1/2}$ for plasma and liver is the elimination half-life ($-phase)

[b] liver retention is expressed as either the time period for which residues persist or as the elimination half-life

[c] the elimination half-life of 350 days is for a single oral dose of 0.02 or 0.15 mg ai/kg; elimination was not biphasic

[d] the elimination half-life of 128 days is the terminal phase for a single oral dose of 0.035 mg ai/kg; elimination was biphasic

[e] cited in Eason et al. (2001)

Table 35. Hepatic Concentrations of Brodifacoum and Bromadiolone in Rats Administered a Single Oral Dose of 0.2 mg ai/kg (adapted from Hawkins et al. 1991)

Days after dosing	Brodifacoum (ppm)	Bromadiolone (ppm)
1	1.107 ± 0.038	0.983 ± 0.049
7	1.078 ± 0.088	0.844 ± 0.051
14	1.121 ± 0.077	0.727 ± 0.098
50	0.838 ± 0.075	0.440 ± 0.042
100	0.679 ± 0.061	0.366 ± 0.026
200	0.539 ± 0.028	0.282 ± 0.041

Table 36. Percentage of a Single Dose of Brodifacoum Retained in the Liver for up to 104 Weeks (adapted from Batten and Bratt 1987)

Time after dosing	% of dose retained per group		
	0.02 mg ai/kg	0.15 mg ai/kg	0.35 mg ai/kg
Day 1	47.3	29.7	28.9
Week 4	39.2	37.1	23.5
Weeks 12-13	34.0	31.7	21.2
Week 65	16.0	15.4	-
Week 104	11.8	11.7	-

Based on those findings, the authors conclude that the existence of biphasic kinetics in the liver for brodifacoum has two important consequences. "Firstly the fast and slow phases can each be characterized by a half-life estimation. It is apparent however that the half-life quoted (approximately 4 days) using data from the fast initial phase of the elimination from the liver can give a misleading impression of the potential persistence of an anticoagulant. If lethal doses were used, tissue concentrations could only be measured prior to death and since this would occur during the rapid elimination phase the subsequent slow phase of elimination would not be apparent. This probably explains why data for bromadiolone, a structurally similar anticoagulant to brodifacoum suggest that this substance is rapidly eliminated from rats (Poché 1986). Secondly, the concentration of radioactivity in the liver at the beginning of the terminal phase is independent of the dose and therefore when expressed as a percentage of the dose decreases as the dose increases. This can give a misleading impression with regard to the size of the residue present."

Parmar et al. (1987) also reported biphasic elimination of radio-labelled brodifacoum and bromadiolone from rat liver. The initial phase occurred from days 2 to 8 after dosing, followed by a prolonged terminal phase when the elimination half-lives were 130 and 170 days for brodifacoum and bromadiolone, respectively. However, the results were presented only in an abstract with too few details provided to adequately evaluate the results reported.

Belleville (1991) orally dosed rats with 0.06 mg ai/kg brodifacoum or difethialone on 4 occasions at weekly intervals. After 6 months, 21% of the total brodifacoum dose and 7% of the total difethialone dose was retained in hepatic tissue (Table 37). Hepatic half-lives calculated for the 158 days after the final dose (days 22 to 180) were 136 days for brodifacoum and 74 days for difethialone.

Table 37. Hepatic Concentrations in Rats Dosed at 0.06 mg ai/kg on Days 0, 7, 14, and 21 (adapted from Belleville 1991)

Time after initial dose	Brodifacoum (ppm)	Difethialone (ppm)
22 days	2.01 ± 0.15	1.28 ± 0.15
49 days	1.50 ± 0.48	0.84 ± 0.15
77 days	0.98 ± 0.32	0.49 ± 0.08
4 months	0.85 ± 0.15	0.35 ± 0.07
6 months	0.87 ± 0.16	0.29 ± 0.08

Studies in species other than rats also indicate that brodifacoum can be retained in animal tissue for a very long time. Eason et al. (1996) detected brodifacoum residue 9 months after administration of a sublethal dose of 0.1 ppm in possums. Laas et al. (1985) examined retention of brodifacoum in sheep tissues and its excretion via feces after a single, sublethal oral dose of either 0.2 or 2.0 mg ai/kg to 14 sheep. Sheep were sacrificed periodically 2 to 128 days after dosing and liver, carcass, and fat tissues analyzed for residue. Brodifacoum was detected in the liver after 128 days, at concentrations of 0.64 and 1.07 mg ai/kg dry weight (equivalent to 0.22 and 0.36 mg ai/kg wet weight), respectively, for the 2 doses. Residue also was detected for up to 8 days in fat and up to 15 days in the carcass. Bromadiolone was detected for 256 days in the liver of sheep that received a sublethal dose of 2 mg ai/kg (Nelson and Hickling 1994). Breckenridge et al. (1985) reported a plasma elimination half-life of about 2.5 days for rabbits dosed with brodifacoum, and Woody et al. (1992) observed an elimination half-life for brodifacoum in serum of 6± 4 days in four dogs. The plasma half-life of brodifacoum determined in three human patients with severe bleeding disorders was found to be approximately 16–36 days (Weitzel et al. 1990).

First-generation anticoagulants

Although fewer data are available for the first-generation anticoagulants (Table 38), the available information indicates they are generally less persistent in the blood and body tissues. Belleville (1981) orally administered radio-labeled chlorophacinone to rats with either a single dose of 1 to 1.26 mg ai/rat (~4 to 6 mg ai/kg) or 3 daily doses of 1.43 mg ai/rat (~6 to 7 mg ai/kg). The compound was rapidly absorbed and metabolized; 90% was excreted within 48 h and 100% within 4 days. Elimination was almost totally via the feces; <1% was via urine and CO_2. The $t_{1/2}$ in blood was 9.8 h, with the maximum concentration attained after 4 to 8 h. The maximum blood concentration in rats that received 3 doses was 1.8 to 3.7 times higher than that from rats receiving a single dose. Concentrations in body tissues after 4 h and 48 hours were highest in liver, but chlorophacinone also was present in kidneys, lungs, heart, muscle, fat, and other parts of the carcass (Table 39).

Yu et al. (1982) studied the metabolism and disposition of diphacinone in rats and mice. In rats given a single oral dose of radiolabeled diphacinone at either 0.18 or 0.4 mg ai/kg, about 70% of the dose was eliminated in feces and 10% in urine within 8 days, whereas about 20% of the dose was retained in body tissues. Mice given a single dose of 0.6 mg ai/kg eliminated most diphacinone within 4 days, and only 7% was retained in body tissues. In both rats and mice, most radioactivity (59 to 69%) was detected in the liver and the kidneys (9 to 12%). Radioactivity also was detected in the brain, heart, spleen, lungs, blood, muscle, fat, and gonads. Several major metabolites were identified, and parent diphacinone in excreta and liver accounted for only about 20% of the dose. In another study, cattle that received a single injection of 1 mg ai/kg had almost constant residue concentrations in liver and kidney at 30, 60, and 90 days after dosing (Bullard et al. 1976). The plasma half-life in humans is reported to be 15 to 20 days (WHO 1995).

Table 38. Persistence of First-generation Anticoagulants in Blood and Liver

Anticoagulant	Species	Dose (mg ai/kg)	No. doses	Blood $t_{1/2}$[a] (days)	Liver retention[a,b] (days)	Reference
Diphacinone	cattle	1.0	1		>90	Bullard et al. 1976
Diphacinone	human			15-20		WHO 1995
Chlorophacinone	rat	4-5	1	0.4		Belleville 1981
Warfarin	rat			0.7 (%) 1.2 (&)		Pyrola 1968[c]
Warfarin	rabbit			0.2		Breckenridge et al. 1985[c]
Warfarin	possum			0.5		Eason et al. 1999
Warfarin	human	0.5-100	1	0.6-2.4		O'Reilly et al. 1963[c]
Warfarin	pig				30-40	O'Brien et al. 1987[c]

[a] $t_{1/2}$ for plasma and liver is the elimination half-life ($-phase)

[b] liver retention is expressed as either the time period for which residues persist or as the elimination half-life

[c] cited in Eason et al. (2001)

Table 39. Chlorophacinone Residue in Rats 4 and 48 hours After an Oral Dose of 1.26 mg ai per Rat (adapted from Belleville 1981)

Tissue	µg ai/g (ppm)	
	4 h after dosing	48 h after dosing
Liver	31.1	2.9
Kidney	6.6	1.2
Lung	4.5	0.4
Heart	3.1	0.2
Muscle (thigh)	2.0	0.1
Fat	1.2	0.7
Carcass	5.2	0.3

Diaz and Whitacre (1976) orally dosed rats with diphacinone (0.32 mg ai/kg/day) for 1 or 2 days. Rats dosed for 2 days were sacrificed 72 h after the second dose and those dosed for 1 day were sacrificed after 48 h. In rats dosed for 2 days, about 45% of the total dose administered was excreted (86% in feces, 14% in urine) and 25% was retained in body tissues 72 h after the last dose. The remaining 30% of the dose was not recovered. The body tissues retaining the most diphacinone at 96 h were the hide and tail, liver, intestine, blood, and the carcass (Table 40). In rats dosed for 1 day and sacrificed after 48 h, about 5% of the dose was excreted and 61% retained; the remained was not recovered.

In contrast to other anticoagulants, especially the second-generation compounds, warfarin is extensively metabolized and the major route of excretion is in the urine. Limited data exist regarding persistence of warfarin in the liver. O'Brien et al. (1987; cited in Eason et al. 2001) found comparatively rapid clearance of warfarin in pigs, with concentrations declining to very low levels after approximately 30 days. Meehan (1984) states that approximately half the warfarin consumed by a rat remains in the body after 6 hours. Thijssen (1995) cites a half-life of 7 to 10 days in animal tissue, and Ford (1993; cited in Poché and Mach 2001) reported a half-life of 42 hours in the gastro-intestinal tract. EPA (1982) noted that only 7.6% of the warfarin consumed in bait by 11 rats remained in the carcass after a 5-day feeding period. According to Machlin (1984; cited in Poché and Mach 2001), warfarin concentrates in the liver, but the adrenal glands, lungs, bone marrow, kidneys, and lymph nodes also contain measurable amounts. Breckenridge et al. (1985) reported a plasma elimination half-life of 5.6 hours in rabbits. O'Reilly et al. (1963) reported that the mean half-life varied from 24 to 58 hours for disappearance of warfarin from the plasma of human volunteers given a single oral dose of 0.5 to 100 mg ai/kg; no dose-dependent effect on half-life was apparent over this range of doses.

Table 40. Percentage of Diphacinone Retained by Rats Dosed For 1 or 2 Days With 0.32 mg ai/kg (adapted from Diaz and Whitacre 1976)

Organ	% of total dose retained[a]	
	48 h after 1 dose	72 h after 2 doses
Intestine	22.1	4.1
Liver	19.4	5.4
Hide and tail	10.9	6.5
Carcass	3.9	3.8
Blood	1.8	4.0
Muscle	0.8	0.4
Kidney	0.7	0.3
Testis	not reported	0.8
Lung	0.5	0.2
Fat	0.2	0.4
Heart	0.1	0.2
Spleen	0.1	0.1
Brain	<0.1	<0.1

[a] because only 66-70% of the total dose was recovered, percentages in tissues are likely to be higher than the values tabulated

Potential Secondary Risks

Birds

Qualitative assessments of potential secondary risks are based on mortality and other adverse effects reported in secondary-hazards tests, information obtained from field studies and operational control programs, toxicokinetic data, residue levels reported in primary consumers, and incidents. Much of the data are presented in preceding sections of this assessment. It can be difficult to extrapolate from laboratory data to wild birds in the field, because of factors such as animal behavior and environmental conditions. However, laboratory tests are not necessarily overly conservative as argued by some registrants. As discussed in the *Final Report of the Avian Effects Dialogue Group, 1988-1993* (AEDG; Rymph 1994), even sublethal effects seen in controlled laboratory conditions might result in decreased survival or reproduction in the field where animals also are exposed to other stressors, and such effects often are overlooked in the risk assessment process. The AEDG notes that "Decreases in the survival or reproduction of birds following acute or chronic pesticide exposures that would be sublethal in the laboratory may result from alterations in physiological condition, motor function and behavior."

Additional information also is available to demonstrate that exposure to rodenticide baits can have adverse effects. Information from field studies and control program is presented below, and incident data that help characterize secondary risks are discussed in an "*Incident Data: Birds and Nontarget Mammals*" section later in the document. Data gaps exist for some of the rodenticides, but some marked differences in potential secondary risk are apparent among the compounds.

Based on the available feeding studies, brodifacoum poses the greatest potential secondary risk to birds. In 11 secondary-hazard studies that exposed 149 raptors or scavengers to brodifacoum-poisoned prey, 42% of exposed birds died. Many survivors exhibited signs of intoxication, including bleeding. Moreover, mortality via secondary exposure is not limited to laboratory tests but has also been widely reported in field studies and brodifacoum control programs (see below). Brodifacoum residue also has been detected in the liver of numerous dead owls, eagles, hawks, and corvids (see Attachment D). Potential risks of difethialone cannot be adequately characterized until secondary-hazard data are available. However, based on its similarity to brodifacoum in chemical structure (Attachment A), physical and chemical properties, acute toxicity profile for birds (Table 3) and mammals (Table 8), and retention times in animal tissue (Table 34), difethialone is presumed to pose comparable risks. Some uncertainty exists due to the lack of hazard data and also because difethialone baits are formulated with less active ingredient (25 ppm) than are brodifacoum baits (50 ppm).

The other anticoagulants also exhibit a potential for secondary risk to birds but not to the same extent as brodifacoum and possibly difethialone. Secondary hazard studies suggest that bromadiolone and diphacinone pose greater potential risks than do chlorophacinone and warfarin, which are less hazardous and less likely to bioaccumulate in body tissues.

Some information is available for zinc phosphide, but additional data are needed to characterize potential secondary risks of bromethalin and cholecalciferol. Studies indicate that zinc phosphide has a low secondary hazard, probably because it is rapidly converted to phosphine gas in the stomach and not retained in toxicologically significant quantities in body tissues of primary consumers. However, undigested bait in primary consumers may pose a hazard to raptors or scavengers that might consume the GIT.

Based on the data from secondary hazard laboratory studies and the data available on retention times in blood and liver of target species, the comparative analysis model indicates that brodifacoum and difethialone pose the greatest potential secondary risks to birds (Table 41). Brodifacoum has higher summary values than difethialone for all three measures of effect. Mean (%) mortality of secondary lab studies appears to be the most significant measure of effect leading to the conclusion that brodifacoum poses substantially greater potential secondary risk to birds than the other rodenticides (Figure 4).

Table 41. Comparative Analysis Model Results for Secondary Risk to Birds

Rodenticide	mg ai/kg bait	Measure-of-effect values			Summary value
		mean mortality (%)[a]	blood retention time (days)[b]	liver retention time (days)[b]	
Brodifacoum	50	42.00	7.30	217.00	8.60
Bromadiolone	50	8.00	1.40	248.00	3.03
Bromethalin	100	No Data	5.60	No Data	2.20
Chlorophacinone	100	0.00	0.40	No Data	0.03

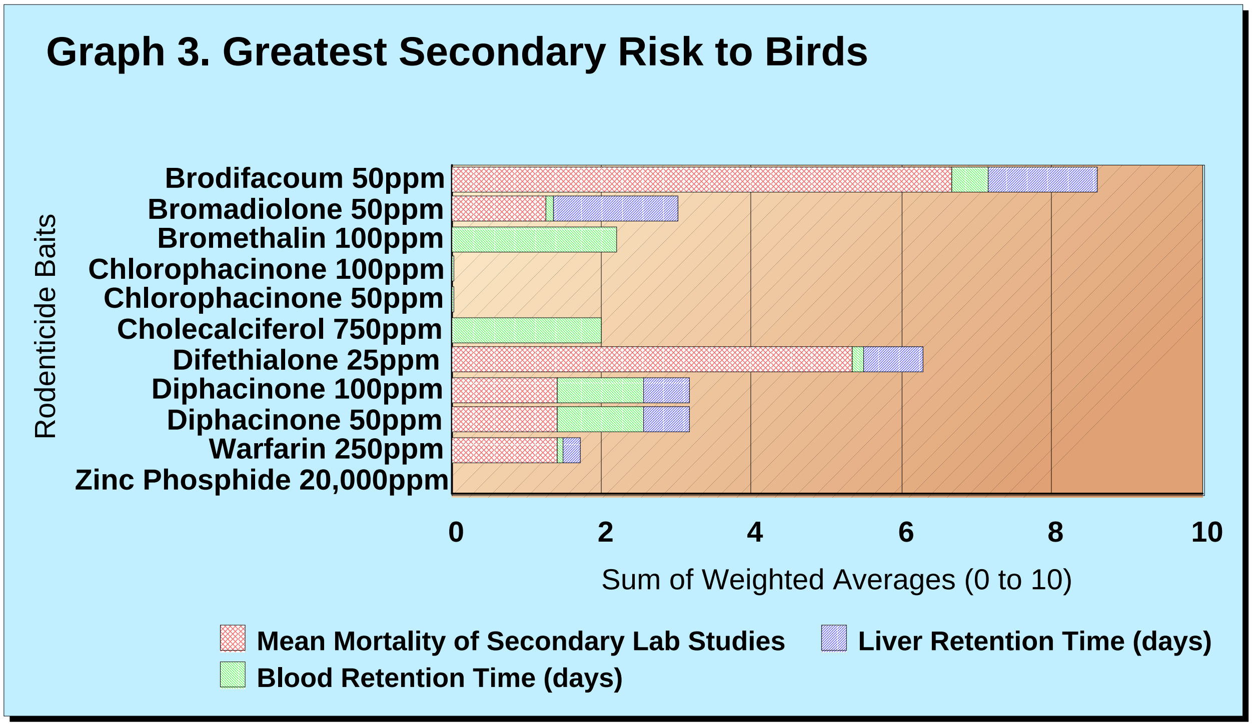
[b] from Tables 13 and 17

[c] as noted in Appendix C, difethialone is considered a special case due to its similarity to brodifacoum; while missing data, it is given a % equal to 80% of that for brodifacoum.

Figure 4. Comparative Analysis Model Summary Values For Secondary Risk to Birds



Information from field studies and control programs: Some information from field studies and control programs is available for some rodenticides, especially brodifacoum. Hegdal and Colvin (1988) examined risk to Eastern screech-owls (*Otus asio*) during experimental baiting for vole control in orchards during the fall and winter of 1981-82. The study indicates considerable risk to screech-owls and possibly other raptors that feed on voles baited with a 10 ppm brodifacoum bait (baits registered for rat and mouse control are 50 ppm). Thirty-two screech-owls were radio-tracked after the baiting. Some owls disappeared or were taken by predators, but the minimum documented mortality of screech-owls was 58% for those individuals for which more than 20% of their home range included treated orchard. Mortality was also considerable (17%) for those owls having less than 10% of their home range including treated areas. Liver-residue analysis was conducted on 16 screech-owls collected or found dead during the study. Although the limit of detection 0.3 ppm was deemed inadequate by the authors, brodifacoum residue was detected at levels ranging from 0.3 to 0.8 ppm in 9 owls., and residue was found in owls collected up to 57 days posttreatment. Death of a long-eared owl (*Asio otus*) also was presumed due to brodifacoum, based on extensive hemorrhage and detection of residue in owl pellets containing vole remains.

Hegdal and Blaskiewicz (1984) found no secondary risk to barn owls residing on New Jersey farms when brodifacoum was applied to control rats and mice from late July to September in 1980. Radio-telemetry data for 34 owls indicated they spent most feeding time hunting for meadow voles in fields and marshes and spent little time foraging for rats and mice around farms. Rats and mice comprised only 3.9% and 2% of the diet, respectively, and owl traps baited with mice and placed around farmsteads were ignored by owls. In contrast, Duckett 1984 (cited in Newton et al. 1999 and Eason and Spurr 1995) reported a major decline in a barn owl population on an oil palm plantation in Malaysia after second-generation anticoagulants were applied for rat control. The owls were feeding on rats and the owl population declined from 40 to 2 individuals.

Howald et al. (1999) examined effects of brodifacoum baiting on avian scavengers during rat control on a Canadian island. They conclude that there is a very real risk of secondary poisoning of some predators and scavengers, and the impact on ravens may have been severe. Thirteen dead ravens were found out of an island population estimated at 20 to 72 individuals. All 13 dead ravens had brodifacoum residue in the liver, with concentrations ranging from 0.98 to 2.52 ppm. Ravens were likely exposed from eating the bait as well as secondarily via prey who had previously fed on the bait. Secondary poisoning is evident from observations of ravens scavenging on rat carcasses and the presence of rat hair in the gizzard of several ravens. Assuming an LD50 of 0.56 mg ai/kg (a value offering 95% species protection for birds) and a rat total-body burden of 1.4 mg ai (based on measured residue concentrations in 10 rats), the authors calculate that a single brodifacoum-poisoned rat could provide 2 to 3 LD50 doses for a raven or crow. No mortality of bald eagles was evident during the baiting program, but exposure occurred. Twenty bald eagles were trapped and 1 other rescued during the baiting program. Brodifacoum was detected at levels of 0.037, 0.041, and 1.74 ppm in the blood plasma of 3 (15%) of 21 eagles sampled. The authors calculated that a bald eagle, because of its large size, would need to eat about 3.2 rats to obtain an LD50 dose.

Based on numerous bird kills during operational control programs with brodifacoum in New Zealand, Eason and Spurr (1995) conclude that the potential for secondary adverse effects is much greater for second-generation anticoagulants than for first-generation anticoagulants. Secondary adverse effects on Australasian harriers (*Circus approximans*), New Zealand falcons (*Falco novaeseelandiae*), rails, brown skuas (*Catharacta skua*), gulls, and owls (morepork, *Ninox novaeseelandiae*) has been reported after brodifacoum baiting (Eason and Spurr 1995, Towns et al. 1993, Ogilvie et al. 1997, Walker and Elliott 1997). Stephenson et al. (1999) studied the fate of moreporks, which feed on mice, after a single aerial application of brodifacoum to eradicate mice on Mokoia Island. Twenty-eight owls were monitored after the baiting, including 14 that were radio-tagged and tracked. Three (21%) radio-collared owls died. Seven (50%) owls not radio-collared disappeared, which the authors believe is most likely a result of secondary poisoning. Two dead owls were analyzed for residue, and brodifacoum was detected in the liver of both at concentrations of 1 and 1.1 ppm.

A survey in Great Britain indicates that exposure of barn owls to second-generation anticoagulants may be frequent and widespread. As part of a pesticide-monitoring scheme, the livers from 717 dead barn owls were analyzed for anticoagulant residue from 1983 to 1996

(Newton et al. 1990, 1999; Wyllie 1995). Although second-generation anticoagulants were detected in 26% of the owls (34 to 37% in the latter years when better analytical methods were available), most deaths resulted directly from collisions with cars and trucks or starvation. However, the authors believe that the proportion of deaths due to rodenticides may have been underestimated. Almost all carcasses had been collected from open areas, such as roadsides. As the authors note, death from anticoagulant exposure is delayed and preceded by lethargy, and most victims are likely to die in their roosts, in roof-cavities or hollow trees, where they are not likely to be found. Also, carcasses found in such locations are most often too decayed to permit tissue analysis. Newton et al. (1990) also note that ". . . there remains the possibility that sub-lethal levels of rodenticide may predispose death from other causes, or reduce the chance of recovery from accidents.", and they emphasize that ". . . more monitoring of residues and population trends is clearly desirable."

No field studies are available for difethialone or bromadiolone. Some information on nontarget exposure to bromadiolone has been reported in France and Switzerland, where bromadiolone is used for control of water voles (*Arvicola terrestris*) and coypu (nutria). From 1991 to 1994, a number of dead birds suspected to have been exposed to anticoagulant rodenticides were submitted for analysis. Bromadiolone was detected in the liver of 15 of 16 dead Eurasian buzzards, 5 of 5 kites (*Milvus migrans*), and the one harrier examined (Berny et al. 1997). Saucy et al. (2001) reported deaths of numerous birds, mostly Eurasian buzzards but also kites and carrion crows, after bromadiolone bait (150 ppm) was mechanically applied in underground burrows for water vole control in Switzerland.

The Agency is not aware of any field tests designed to assess secondary risk to raptors from first-generation anticoagulants or the non-anticoagulants. Several field tests designed to assess the efficacy of chlorophacinone and zinc phosphide included searches for nontarget carcasses as a secondary objective. None found any indications that raptors or avian scavengers were killed from feeding on target species previously exposed to the rodenticides. However, most search effort was devoted to locating nontarget carcasses on and immediately around baited plots. Because raptors may be wide-ranging and anticoagulants are slow-acting, radio-tracking individual birds is essential to evaluate their interactions with the target species and to determine their fate (Fagerstone and Hegdal 1998, Colvin et al. 1991, Colvin et al. 1988, Edwards et al. 1988).

Nontarget mammals

Based on a qualitative assessment of potential secondary risk to mammals from feeding studies, all 6 anticoagulants appear to pose a potential secondary risk to mammalian predators and scavengers, although warfarin apparently less so than the others. Secondary risks from zinc phosphide appear to be low for most species, especially those that don’t consume the GIT where undigested bait may be present. Too few data are available to adequately assess potential risks of either bromethalin or cholecalciferol.

The comparative analysis model results indicate that diphacinone, chlorophacinone, and brodifacoum pose the greatest potential secondary risk to mammals (Table 42). Retention time in blood was the most significant measure of effect leading to the conclusion that diphacinone poses greater potential secondary risk than does chlorophacinone, while mean (%) mortality of secondary lab studies was the most significant measure of effect leading to the conclusion that both diphacinone and chlorophacinone poses greater potential secondary risk than does brodifacoum (Figure 5).

Table 42. Comparative Analysis Model Results for Secondary Risk to Mammals

Rodenticide	mg ai/kg bait	Measure-of-effect values: mean mortality (%)[a]	blood retention time (days)[b]	liver retention time (days)[b]	Summary value

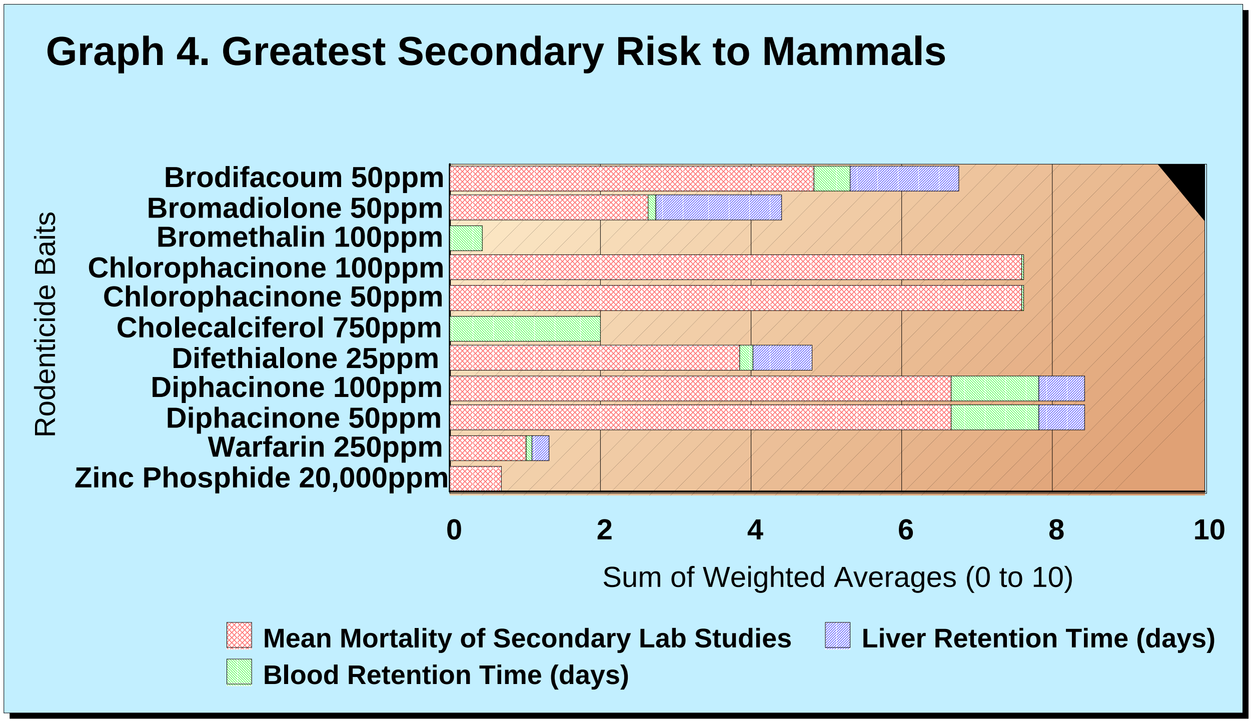
[c] as noted in Appendix C, difethialone is considered a special case due to it's similarity to brodifacoum; while missing data, it is given a % equal to 80% of that for brodifacoum.

Figure 5. Comparative Analysis Model Summary Values For Secondary Risk to Nontarget Mammals



Information from field studies and control programs: The Agency is not aware of any field studies designed to assess secondary risks to mammals, but exposure and mortality has been documented in some situations. Extensive mortality of introduced mammalian predators was reported during brodifacoum-baiting operations for rats in New Zealand forests. Mortality of stoats (ermine), ferrets, weasels, and cats was reported to be 100% after brodifacoum application (Alterio 1996, Alterio et al. 1997; cited in Stephenson et al. 1999). In one study, all 11 radio-collared stoats and the 1 radio-collared weasel died within 9 days of bait application. In another study, Murphy et al. (1998) detected brodifacoum residues in the liver of 56% of 16 feral ferrets, 78% of 40 stoats, and 71% of 14 weasels examined after baiting.

Some information on nontarget exposure of mammals to bromadiolone was obtained during vole and coypu control in France (Berny et al. 1997). Bromadiolone was detected in the liver of 22 of 31 red foxes (*Vulpes vulpes*), 4 of 28 rabbits (*Oryctolagus cuniculus*) and hares (*Lepus capensis*), 3 of 6 wild boar (*Sus scrofa*), 2 roe deer (*Capreolus capreolus*), 2 stone martens (*Martes foina*), a lynx (*Lynx lynx*), and a badger (*Meles meles*). Based on the species involved, secondary poisoning seems to have been the predominant route of exposure. Saucy et al. (2001) reported deaths of 38 wild mammals, mostly red foxes and mustelids, and 18 cats and dogs after bromadiolone bait (150 ppm) was mechanically applied in underground burrows for water vole control in Switzerland.

Second-generation anticoagulants were detected in the liver of 31% of 29 polecats (*Mustela putorius*) analyzed from 1992 to 1994 in Britain (Shore et al. 1996, Newton et al. 1999). Most of the carcasses collected were found along roadsides. The authors believe the survey results indicate exposure of polecats to second-generation rodenticides may be common, and they suggest that studies to determine potential effects of such exposure are warranted.

Savarie et al. (1979) orally dosed 10 wild coyotes with diphacinone, with doses ranging from 0.31 to 5 mg ai/kg. Radio collars were attached to these animals, and they were released back into the wild and monitored for survival. Seven (70%) of the 10 coyotes died within 7 to 16 days, with an average time to death of 9.6 days.

Incident Data: Birds and Nontarget Mammals

Ecological Incidents Information System (EIIS)

Incident reports submitted to the Agency indicate that birds and nontarget mammals are being exposed to rodenticides, especially brodifacoum. EFED’s EIIS contains information on more than 300 incidents in which one or more of the rodenticides was detected in birds or nontarget mammals (Table 43 and Attachment D). Brodifacoum was detected in more than 244 of those, including 25 of 26 involving exposure to more than one rodenticide. Bromadiolone was detected in 39 incidents, including 17 that also involved exposure to brodifacoum. Twenty-five incidents are reported for zinc phosphide, 20 for diphacinone, 13 for chlorophacinone, 4 for warfarin, 1 for difethialone, and none for bromethalin or cholecalciferol. Eleven of the incidents for the first-generation anticoagulants also included exposure to a second-generation anticoagulant, usually brodifacoum. Approximately 80 additional incidents involving raptors exposed to anticoagulant rodenticides, mostly brodifacoum (84%), have been reported by Stone et al. (2003). The New York State Department of Environmental Conservation has committed to providing those incident reports to EFED, and they will be added to the EIIS database when received.

Other anticoagulant-rodenticide incidents in the EIIS include rodents (mostly tree squirrels), opossums, and deer. Seven deer in New York state tested positive for anticoagulants, including 5 with brodifacoum and 2 with diphacinone. The deer apparently were exposed due to misuse and careless bait application.

Zinc phosphide was implicated in the deaths of some wild turkeys, waterfowl (especially geese) and a few squirrels and a rabbit. In most incidents, treated bait was present in crop or gizzard contents. Two red foxes also apparently died after eating mice who fed on zinc phosphide treated grain.

Table 43. Comparative Number of Reported Rodenticide Nontarget Incidents[a]

Rodenticide	Total[b]	Owls	Diurnal raptors	Corvids	Other birds	Wild canids	Wild felids	Other carnivores	Deer	Rodents/ Rabbits	Opossum
Second-generation anticoagulants											
Brodifacoum	244[c]	54	68	17	4	48	5	10	5	31	2
Difethialone	1	0	0	0	0	0	1	0	0	0	0
Bromadiolone	39	13	5	1	2	5	1	3	0	8	1

Chlorophacinone	13	0	1	0	2	5	1	0	0	4	0
Diphacinone	20	3	2	0	1	4	1	2	2	5	0
Warfarin	4	1	2	0	0	0	0	0	0	1	0
Others (non-anticoagulants)											
Bromethalin	0	0	0	0	0	0	0	0	0	0	0
Zinc Phosphide	25	0	0	0	22	1	0	0	0	2	0
Cholecalciferol	0	0	0	0	0	0	0	0	0	0	0

[a] based on confirmed exposure (e.g., detection of anticoagulant in the liver, zinc phosphide in crop contents); see Attachment B for additional details

[b] 26 incidents involved exposure to more than 1 registered anticoagulant

[c] Syngenta reported two incidents in 6(a)(2) aggregate reports; the species and number of individuals involved were not reported for these incidents

Most of the incidents in the EIIS occurred in New York and California, where state agencies have taken the time, effort, and expense of screening the liver of dead animals suspected to have been killed by rodenticides. Few other states appear to do so, although Wisconsin has reported several raptor incidents. A proper evaluation of rodenticide exposure requires necropsy of a dead animal by a wildlife pathologist. Liver tissue be extracted, frozen, and shipped to an analytical laboratory for analysis by high performance liquid chromatography (HPLC). Because so few anticoagulant screens are conducted, exposure of birds to anticoagulants is likely much more widespread than the number of incidents suggests. Most rodenticide incidents likely go undetected except in those rare instances when a predator carcass happens to be exposed in an open area (e.g., roadside) where it is observed by someone willing to take the time and effort to report it to the proper authorities (McDonald et al. 1998, Newton et al. 1999). In many situations, carcasses might not be detected, death may be attributed to natural mortality, or an incident may not be reported for a variety of reasons, including ignorance, apathy, or failure of authorities to investigate and confirm the cause of death (Rymph 1994, Vyas 1999).

The incidents reported in the EIIS are based on confirmed exposure to a rodenticide. Anticoagulants are detected from residue analysis of liver tissue, supplemented by gross pathological findings. According to Stone et al. (1999), the most frequent pathological signs observed in birds (>50% of individuals examined) exposed to anticoagulants are subcutaneous hemorrhage and overall pallor. Occasional signs (10 to 50% of individuals) include inter/intra-muscular hemorrhage, free hemorrhage in the body cavity, excessive bleeding from minor wounds, and low blood volume in the heart and major blood vessels. Toxicosis resulting from exposure to non-anticoagulants may be more difficult to confirm than for an anticoagulant. Zinc phosphide is generally detected by the presence of dyed bait in the crop, stomach, or alimentary canal. The presence of an acetylene odor also is diagnostic of zinc phosphide toxicity but can be detected only if intact carcasses are sent to an examining laboratory soon after death (Michigan Wildlife Diseases Manual, undated). Little information is available on methodology for detecting bromethalin or cholecalciferol in body tissues.

Anticoagulant rodenticides, especially brodifacoum, have been detected in numerous predators and scavengers. Avian species most commonly exposed are great horned owls and red-tailed hawks. Multiple incidents also have been reported for golden and bald eagles, corvids, barn owl, eastern screech-owl, northern spotted owl, Cooper’s hawk (*Accipiter cooperii*), red-shouldered hawk, sharp-shinned hawk (*Accipiter striatus*), peregrine falcon (*Falco peregrinus*), American kestrel, and vultures. Other incidents have included a long-eared owl, a barred owl (*Strix varia*), a snowy owl (*Nyctea scandiaca*), and a spotted owl (*Strix occidentalis*). Carnivores exposed include coyotes, various foxes (including the endangered kit fox), raccoons, bobcats, skunks, mountain lions, and a weasel. Brodifacoum was detected most often, followed by bromadiolone, chlorophacinone, and diphacinone. Difethialone was detected in 1 dead bobcat.

The American Society for Prevention of Cruelty to Animals (ASPCA) Poison Control Center also has some incident information for pets, mostly dogs. The Center reports 2334 cases involving potential exposure of 2685 animals from November 01, 2001 to June 16, 2003 (S. Hansen, Senior Vice President, pers comm.). By rodenticide, the number of cases were 1161 for brodifacoum, 511 for bromadiolone, 218 for zinc phosphide, 206 for diphacinone, 66 for bromethalin, 48 each for difethialone and warfarin, 42 for chlorophacinone, and 34 for cholecalciferol. EFED does not assess risks to pets, and these data are not a component of the EIIS. However, they do augment the wildlife incident data in demonstrating that nontarget animals are being exposed to some rodenticides, despite product-label use directions to apply bait in locations out of reach of children, pets, domestic animals and nontarget wildlife, or in tamper-resistant bait stations.

The Rodenticide Registrants Task Force (Kaukeinen et al.2000) believe that rodenticide incidents are few when compared to other sources of wildlife mortality. They note that diseases accounted for most of the mortality reported by the National Wildlife Health Center (NWHC) from July 1998 through March 1999 and that there is only a single rodenticide incident. This is not surprising, because the NWHC focuses on diseases and does not analyze wildlife carcasses for rodenticide residues (A. Schrader, NWHC, pers comm.). The Rodenticide Registrants Task Force also contend that bird deaths from collisions with television and radio towers, starvation, and parasitism far exceed deaths attributable to rodenticides. However, small birds such as sparrows, starlings, and other songbirds far outnumber predatory birds such as owls, hawks, and eagles in such incidents. The latter are more likely to comprise incidents attributed to rodenticide toxicity and are more likely to be found and reported. Based on an analysis of the EIIS by Mastrota (1999), brodifacoum was surpassed only by diazinon in the number of wildlife incidents reported for pesticides from 1994 through 1998, the latest period analyzed.

New York State Raptor Incidents

Stone et al. (1999, 2003) provide some perspective on the extent of exposure on some raptor species. They reported 26 cases of anticoagulant poisoning of raptors in New York State from 1994 to 1997, of which 23 (88%) involved brodifacoum. The incidents comprised 17% of all diagnoses for great horned owls (n = 59) and 6% of all diagnoses (n = 114) for red-tailed hawks during that period. For the period 1998 through 2001, they detected anticoagulant rodenticide in 49% of the 265 raptors analyzed in New York State (Table 44). Brodifacoum was detected in 84% of the positive cases and bromadiolone in 22%. One or more anticoagulants were detected in 12 of 19 species examined, with most detections made in great horned owls (81%), red-tailed hawks (58%), Cooper’s hawks (36%), and screech owls (45%). Mean residue levels in those 4 raptor species are presented in Table 45. The data are not sufficient to determine if these exposures are impacting local or state-wide populations of these species via mortality or reduced reproductive success, but they do indicate a need for a sound monitoring program to determine potential adverse effects of such exposure.

Table 44. Detection of Anticoagulant Rodenticides in Liver Tissue of Raptors and Vultures In New York State From 1998 Through 2001 (from Stone et al. 2003)

Species	no. analyzed	no. with anticoagulant rodenticide	% positive detects
Red-tailed hawk	78	45	58
Great horned owl	53	43	81
Cooper’s hawk	50	18	36
Screech owl	22	10	45
Barred owl	13	3	23
Long-eared owl	7	2	29
Turkey vulture	2	2	100
Golden eagle	1	1	100
Bald eagle	5	1	20
Sharp-shinned hawk	11	1	9
Saw-whet owl	3	1	33
Peregrine falcon	2	1	50
Broad-winged hawk	11	0	0
Snowy owl	2	0	0
Northern goshawk	1	0	0
Rough-legged hawk	1	0	0
Merlin	1	0	0
Short-eared owl	1	0	0
Black vulture	1	0	0

Table 45. Anticoagulant Rodenticide Residues In Four Raptor Species Analyzed by Stone et al. (2003)

Anticoagulant/ Raptor species	no. detects	0 liver residue (ppm)	liver residue range (ppm)
Brodifacoum:			
Red-tailed hawk	42	0.21	0.006-1.28
Great horned owl	42	0.21	0.007-0.97
Screech owl	8	0.16	0.007-0.47
Cooper's hawk	12	0.10	0.008-0.22
Bromadiolone:			
Red-tailed hawk	6	0.23	0.08-0.50
Cooper's hawk	5	0.35	0.04-0.60
Diphacinone:			
Red-tailed hawk	1	0.34	
Cooper's hawk	1	0.10	
Warfarin:			
Great horned owl	1	0.73	
Cooper's hawk	1	0.10	
Chlorophacinone:			
Red-tailed hawk	1	0.18	

Endangered San Joaquin kit fox

Of particular concern are findings over the past several years that the endangered San Joaquin kit fox is being exposed to rodenticides, especially brodifacoum. From 1999 to 2003, liver tissue from 32 dead kit foxes has been screened for rodenticide residues by the Pesticide Investigations Unit of the California Department of Fish and Game and by the U. S. Fish and Wildlife Service (R. Hosea, pers. comm.). Anticoagulant rodenticide was detected in the liver of 27 (84%) foxes. Brodifacoum was detected in all 27 individuals. Bromadiolone also was detected along with brodifacoum in 2 of those foxes, and chlorophacinone and pival were found with brodifacoum in 1 fox each. Pival is no longer registered but may have been used under existing-stocks provisions.

Liver residue levels

Uncertainty exists as to what liver concentration might corroborate death or other adverse effects from anticoagulant exposure or even if such a cause-effect relationship is appropriate. The Rodenticide Registrants Task Force proposes a "threshold of toxicity" of 0.7 ppm for brodifacoum in liver tissue (Kaukeinen et al. 2000, Anonymous 2001). However, the proposed threshold level is based on only 2 laboratory studies with a total of 8 barn owls and some selected field surveys. Variation in susceptibility of different bird species, mammals, and other rodenticides is not addressed. Brodifacoum concentrations less than 0.7 ppm have been associated with toxicosis. Eason et al. (1996), for example, dosed 6 brushtail possums with a dose of 0.1 mg ai/kg and reported that 1 animal that died had a liver concentration of only 0.1 ppm brodifacoum. In another study, possums were offered brodifacoum baits for 3 nights (C. Eason, pers comm.). Mean bait consumption of 165.1 g, equivalent to 0.86 ± 0.04 mg ai/kg brodifacoum (range 0.33 to 1.09 mg ai/kg), provided a lethal dose. Extensive hemorrhaging was observed. The mean concentration in the liver was 0.56 mg ai/kg (range 0.17 to 1.04 mg ai/kg), and most animals that died had a liver concentration below the Rodenticide Registrants Task Force's proposed threshold level of 0.7 mg ai/kg. Hegdal and Colvin (1988) collected dead screech-owls during a brodifacoum-baiting study in Virginia; 8 of 9 dead owls with detectable residue had a level <0.7 ppm, and most had hepatic concentrations ranging from 0.3 (the limit of detection) to 0.5 ppm. Those authors also note that other wildlife has been killed in which brodifacoum liver residues were as low as 0.05 ppm (e.g., Rammell et al. 1984). Brown et al. (1996), in their review entitled "*Identification of pesticide poisoning in wildlife*", state that anticoagulant residues remaining after death are usually above or around 0.1 ppm.

A recent incident in Georgia correlates low levels of liver residue with deaths of a red-tailed hawk and a barn owl. These birds and several other raptors were housed in mews at the Amicalola Falls State Park. In November of 2003, the hawk and owl began showing abnormal physical and behavioral symptoms, and both birds died within a few days. Two other great horned owls later showed similar symptoms and were treated with vitamin K. A dead rat was also discovered in a hole in the back of one of the raptor cages. Second-generation anticoagulant rodenticides were in used at the park at the time of the incident to control rats around a lodge and intern housing. Necropsy of the bird carcasses by the Southeastern Cooperative Wildlife Disease Study, The University of Georgia, found moderate to severe clavarial hemorrhage in both birds and moderate focal myocardial hemorrhage in the barn owl. Microscopic examination also showed moderate to severe multifocal hemorrhage in the owl. Microbiological tests were negative. A fresh liver and kidney samples from each bird were screened for heavy metals and organic chemicals, including anticoagulant rodenticides. The only chemical detected in either bird was brodifacoum, with concentrations measured in the at 0.077 ppm in the hawk and 0.007 ppm in the owl. Despite the very low levels detected, the evidence of this case strongly indicates that the birds died from secondary poisoning by feeding on rats exposed to brodifacoum.

Hosea et al. (2001) demonstrate the importance of a proper necropsy in a case where a low liver-residue concentration (0.04 ppm) in the liver determined that brodifacoum caused the death of a golden eagle in California:

> "The carcass of an adult Golden Eagle was recovered from its breeding territory in Contra Costra County on March 11, 1999 (DFG case accession # P-2060A). The bird had been part of a long term radio telemetry study of eagles in the area. Based on telemetry data the breeding territory consisted mainly of open rangeland and random outbuildings with some areas of urban development.
>
> "The bird was not recovered in the vicinity of power lines and the feathers did not have the "singed" odor characteristic of accidental electrocution. The necropsy indicated no other evidence of physical trauma. The animal was skinned to determine the presence of puncture wounds from conflicts with other eagles or from a gunshot. The pericardial sac contained serum and blood. Approximately 65% of the surface of the heart muscle was haemorrhagic. The major vessels associated with the heart contained unclotted blood. The lung tissue was haemorrhagic, bleeding from a cut surface. the cerebro-spinal fluid was blood stained, indicating cranial haemorrhage. These clinical signs were consistent with previously published symptoms of anticoagulant toxicosis in raptors (Hegdal et al. 1988, Mendenhall and Pank 1980, Newton et al. 1990, Radvanyi et al. 1988). Liver tissue was analyzed for residues of anticoagulant rodenticides. Kidney tissue was also analyzed for lead concentrations. Kidney tissue had a lead concentration of 1.1 ppm, well below the level that would indicate acute toxicosis (Aiello 1998). Liver tissue had a brodifacoum concentration of 0.04 ppm. The presence of the rodenticide in liver tissue alone does not support a diagnosis of anticoagulant toxicosis. However, if considered in conjunction with the observed clinical signs consistent with anticoagulant toxicosis, a diagnosis of anticoagulant toxicosis is supported."

C. Eason (pers comm.) provided data depicting the range of brodifacoum concentration in various birds collected dead in areas where brodifacoum was applied in New Zealand. A total of 66 (63%) out of 105 birds found dead and 33 (40%) out of 82 collected alive contained brodifacoum residue (Table 44). As might be expected, brodifacoum residues were found in higher concentrations in birds found dead than in birds collected alive. Many dead birds had a liver concentration <0.7 ppm.

Taken together, findings from the field and the incident data indicate that the liver is an appropriate organ for determining exposure of birds and mammals to anticoagulant rodenticides. However, establishing a toxicity threshold of 0.7 ppm seems to be inappropriate and is not supported by the available data on mortality. Moreover, a toxicity threshold would need to account for adverse sublethal effects (e.g., reproductive, chronic).

Table 44. Brodifacoum Residues Detected In the Liver of Birds In New Zealand (compiled by C. Eason; data obtained from the New Zealand National Vertebrate Pesticide Database and Towns et al. 1994, Morgan et al. 1996, Ogilvie et al. 1997, Dowding et al. 1999, Empson and Miskelly 1999, Robertson et al. 1999, and Stephenson et al. 1999)

The liver is only one of many organs and tissues in which anticoagulant residue accumulates in the body. Concentrations in the liver are often, but not always, higher than in other tissues (e.g., Tables 39, 40, 46, 47). However, because the liver comprises only about 4 to 7% of the weight of a rat or mouse (Newton et al. 1990, Howald et al. 1999), most residue actually may be stored in other parts of the body. For example, Newton et al. (1990) reported a much higher mean residue concentration in liver (2.13 ppm) than in the remainder of the carcass (0.36 ppm) of 10 mice fed brodifacoum bait. However, the mean total amount of residue in the carcass (excluding the liver) was 11.85 µg ai versus only 3.51 µg ai in the liver (Table 47).

Table 46. Tissue Residues in Nine Captive Coyotes Killed With a Single Oral Dose of Diphacinone (adapted from Savarie et al. 1979)

Dose (mg ai/kg)	Tissue residue (ppm)					
	liver	small intestine	kidney	heart	muscle	fat
10	1.2	1.8	0.6	0.5	0.2	<0.1

7	5.67	3.64	9.77	0.28
8	6.72	2.85	19.83	0.58
9	2.70	1.86	5.37	0.18
10	2.44	1.97	11.88	0.35
mean	3.51 ± 0.66	2.13 ± 0.33	11.85 ± 1.54	0.36 ± 0.05

The "threshold of toxicity" concept (Kaukeinen et al. 2000, Anonymous 2001) also assumes that mortality is the only endpoint of concern. A sublethal dose of anticoagulant can produce significant clotting abnormalities and some hemorrhaging (Eason and Murphy 2001), and such effects might be especially detrimental if combined with other stressors that have additive or synergistic adverse effects. Jaques (1959) reported that stress is a hemorrhagic factor in rabbits and rats, and it could be induced by a variety of factors (e.g., frostbite, insulin, NACL). Only 6% of his rats died after 5 days of exposure to an anticoagulant compound (dicoumarol), but 50% died when exposed to the anticoagulant and additional stressors. Others have speculated that birds exposed to anticoagulants may become more susceptible to environmental stressors, such as adverse weather conditions, food shortages, and predation (Hegdal 1985, Hegdal and Colvin 1988, LaVoie 1990). Newton et al. (1999) have speculated that sublethal levels of rodenticide might predispose death from other causes (e.g., collisions with automobiles, starvation) or may reduce the chance of recovery from accidents.

Three golden eagles (*Aquila chrysactos*) recently died in captivity during relocation from the California Channel Islands (J. Linthicum, The Santa Cruz Predatory Bird Research Group [TSCPBRG], pers. comm.). Necropsies were performed and tissues analyzed for a variety of contaminants. Hemorrhaging in lung and brain tissue was reported in 2 birds, and brodifacoum was detected in the liver (0.004 to 0.026 ppm) of all 3 birds. TSCPBRG has trapped hundreds of golden and bald eagles as part of various studies and never previously had an injury or fatality. SCPBRG noted that "Birds of prey, in particular golden eagles, are hardy, tough animals." and

"Nothing in our experience or other's we have spoken to suggest that these birds should have died under these circumstances." Brodifacoum can't be directly implicated in the deaths of the 3 golden eagles, but concern exists. These birds might have succumbed to brodifacoum when augmented by additional stresses from handling and captivity.

Papworth (1959), in discussing the mechanism of anticoagulant toxicity, speculated that a slight scratch, bruise, or even a minor internal injury might lead to death from hemorrhage if clotting is inhibited over an injured surface. Some incidents reported to the Agency suggest that raptors exposed to anticoagulants can be in danger of excessive bleeding from minor wounds caused by their prey. Such wounds, not normally life-threatening, may cause prolonged bleeding and mortality when blood-clotting mechanisms are disrupted. One great horned owl exposed to brodifacoum (0.64 ppm liver residue) was collected near death on a farm where brodifacoum bait had been applied in barns and sheds. This owl was almost completely exsanguinated from a small laceration on a toe. Other owls and hawks found dead had bled excessively from minor wounds, usually on their feet, likely inflicted by prey (see Attachment D). A partially eaten muskrat was found by one dead owl that appeared to have bled excessively from a puncture wound extending from between the eyes into the sinuses. Brodifacoum was detected in the liver of these raptors at concentrations ranging from 0.08 to 0.80 ppm. Bromadiolone also was detected in 1 owl.

Some of the concerns and uncertainties regarding possible adverse sublethal effects can be addressed through avian reproduction studies, which the Agency will require for all pesticides with outdoor uses. The no-observable-adverse-effects concentration (NOAEC) established from these studies will be a more appropriate indicator of a toxicity threshold than is the liver residue in dead animals.

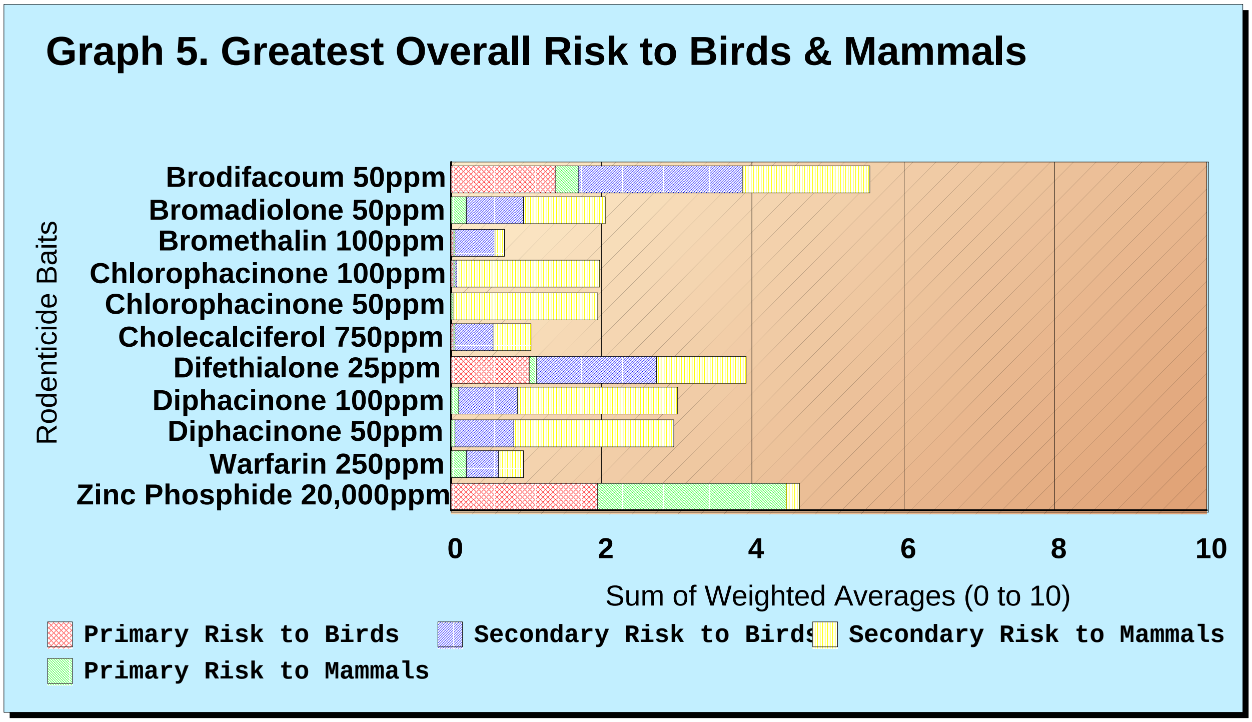
Conclusions

The available information indicates that differences exist among these rodenticides in their potential risks (primary and secondary) to birds and nontarget mammals. Based on the comparative analysis model, comparing measures of effect for primary and secondary risks to birds and mammals, brodifacoum, zinc phosphide, and difethialone are ranked as the rodenticides posing the greatest potential overall risk (Table 48, Figure 6).

Table 48. Comparative Analysis Model Results for Overall Risk to Birds and Mammals. Tabulated values are weighted measures of effect.

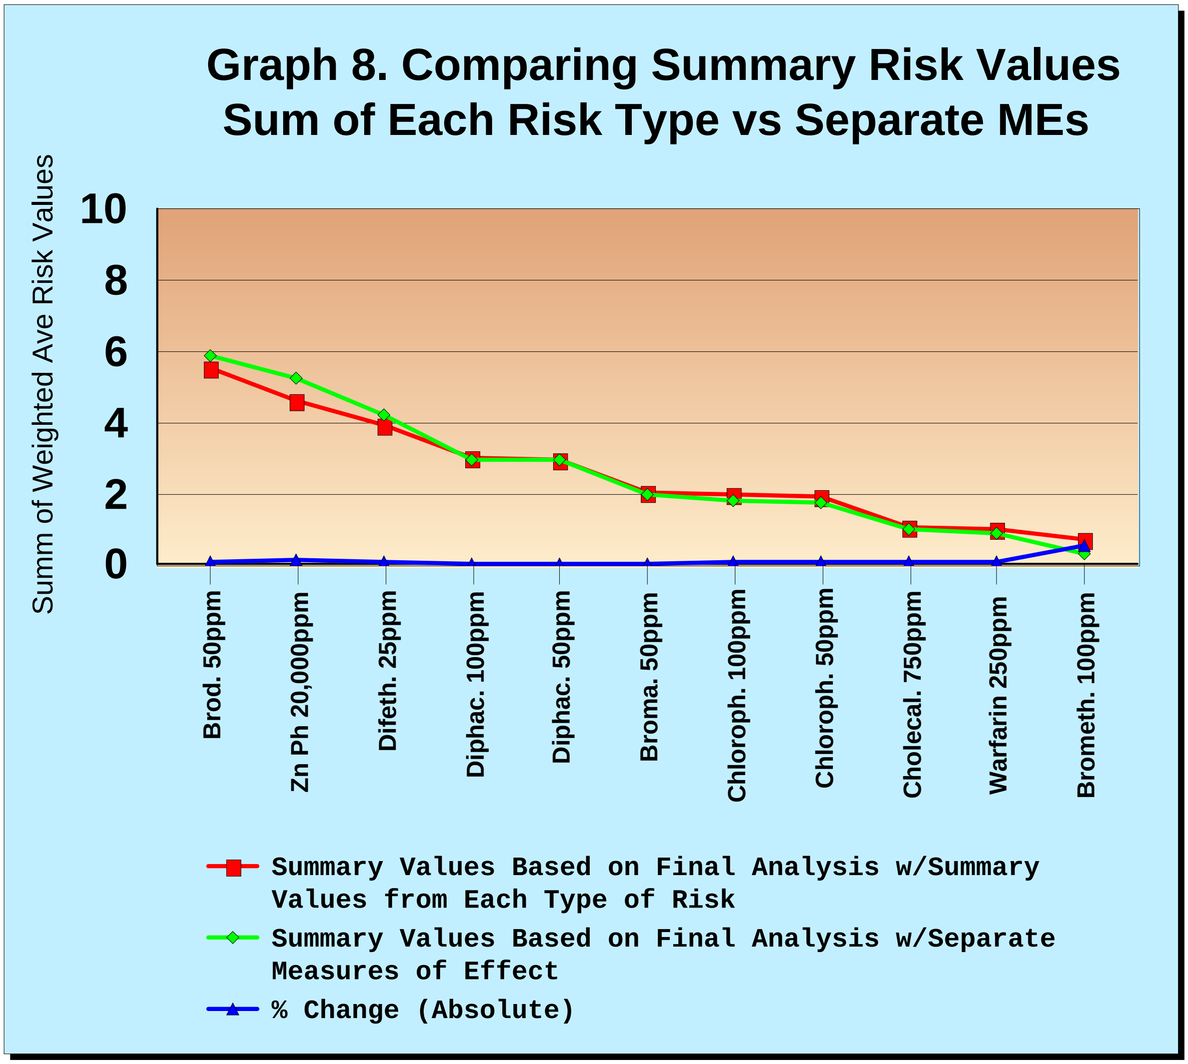
Rodenticide	mg ai/kg bait	Primary risks		Secondary risks		Summary values
		birds	mammals	birds	mammals	
Brodifacoum	50	5.58	1.25	8.60	6.76	5.55
Bromadiolone	50	0.10	0.71	3.03	4.40	2.06
Bromethalin	100	0.10	0.10	2.20	0.44	0.71
Chlorophacinone	100	0.14	0.16	0.03	7.62	1.99
Chlorophacinone	50	0.07	0.08	0.03	7.62	1.95
Cholecalciferol	750	0.12	0.18	2.00	2.00	1.07
Difethialone	25	4.15	0.45	6.29	4.82	3.93
Diphacinone	100	0.01	0.43	3.18	8.42	3.01
Diphacinone	50	0.01	0.22	3.18	8.42	2.96
Warfarin	250	0.04	0.83	1.72	1.32	0.98
Zinc Phosphide	20,000	7.81	10.00	0.00	0.69	4.63

Figure 6. Comparative Analysis Model Summary Values For Overall Risks to Birds and Nontarget Mammals



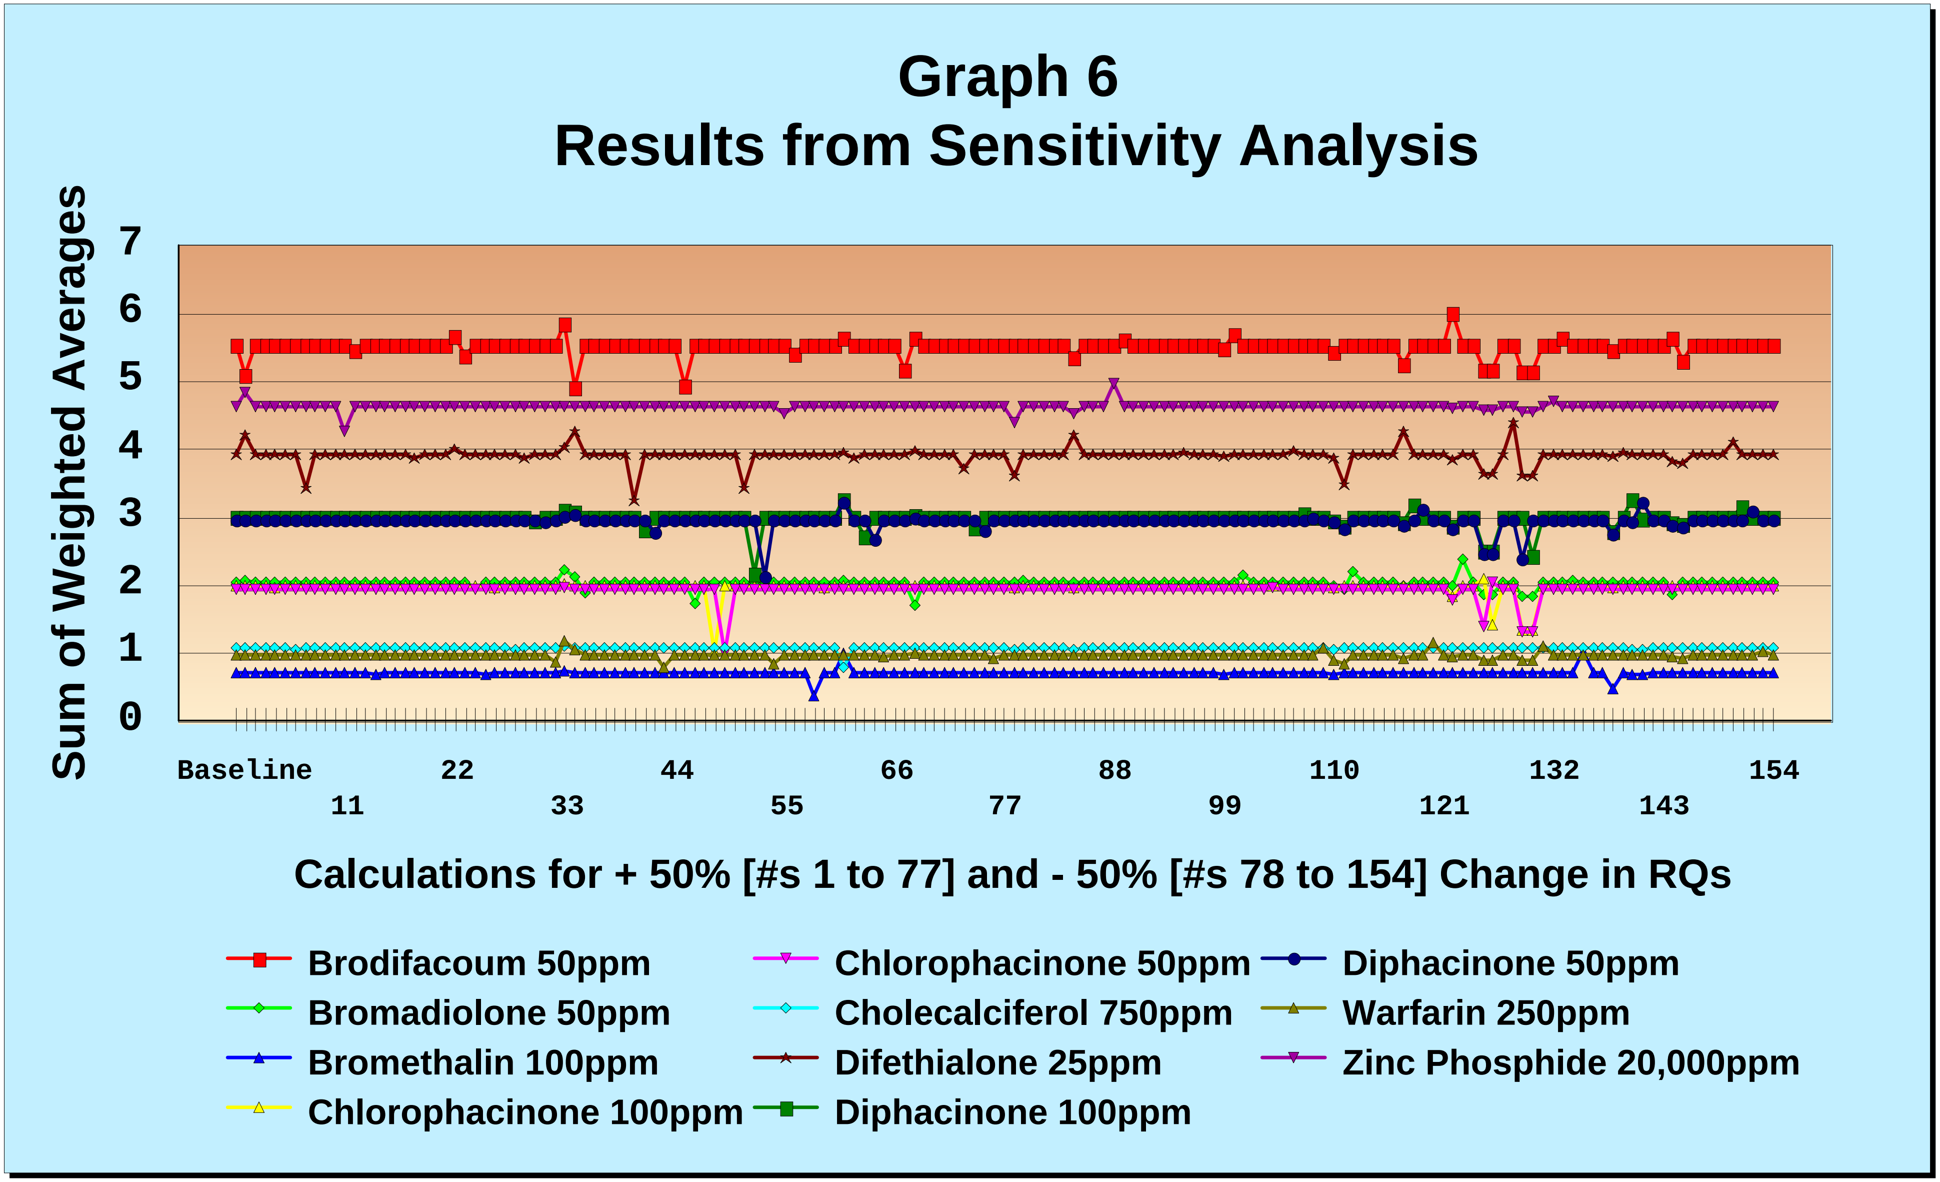
The approach taken for the overall analysis is to analyze each risk type separately, then analyze the summary values for each of the four risk types together. Each type of risk included variable and unequal numbers of measures of effect. Analyzing them separately and using summary values to derive an overall risk value eliminates unequal weighting of one risk over another due to differences in the number of measures of effect. An alternate approach is to consider all measures of effect in a single step and ignore unequal weighting. This alternate approach did not result in a change in the rankings (see Fig. 6).

Figure 7. Comparative Analysis Model Results Summary Values For Overall Risks When All Measures of Effect Are Considered in One Step



The sensitivity analysis (Fig. 7) indicates that the comparative analysis model rankings are robust, especially for brodifacoum, zinc phosphide and difethialone. Their ranking as the three rodenticides posing the greatest overall potential risk do not change when values for the measures of effect are varied by ±50%. See Appendix C for additional details of the sensitivity analysis.

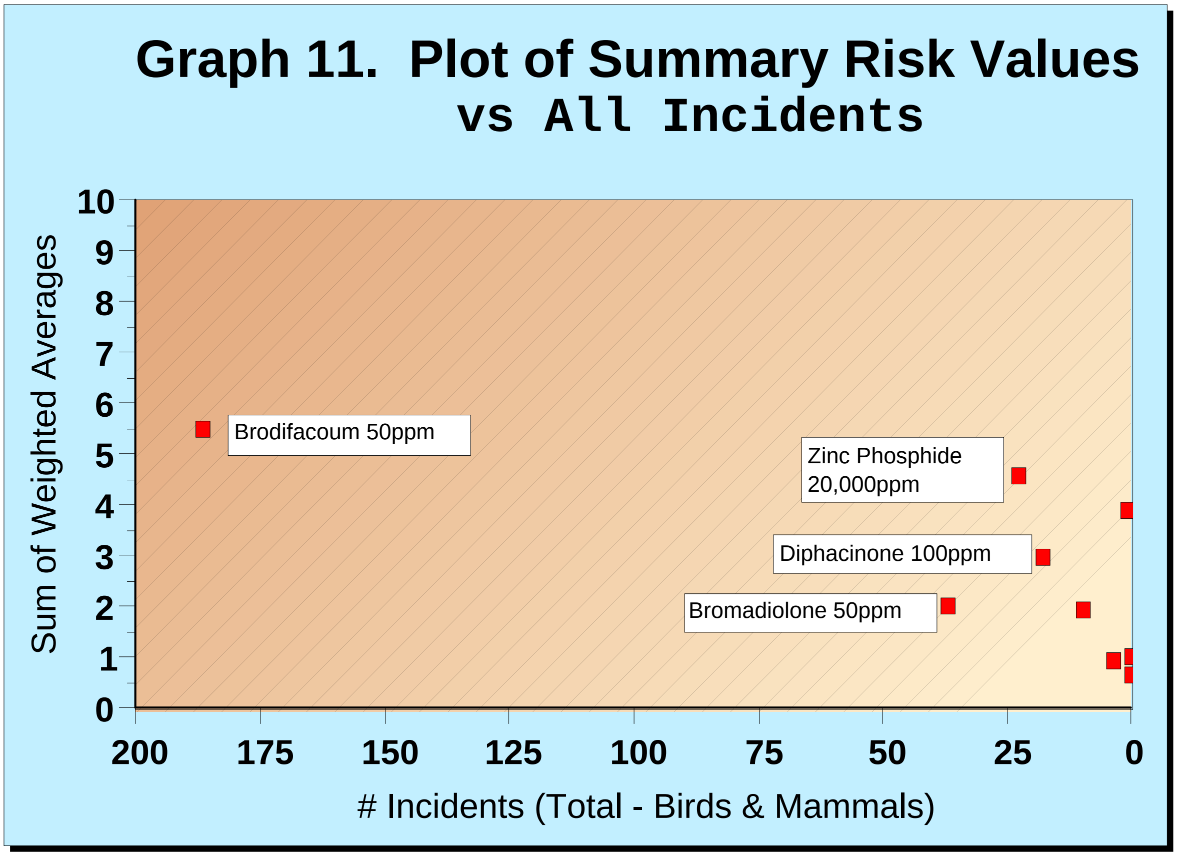
Figure 8. Sensitivity Analysis of Measure-of-effect Values Used in the Comparative Analysis Model. Each measure-of-effect value is separately decreased by 50% and then increased by 50%.



Lack of data for some rodenticides accounts for the most uncertainty in the comparative analysis model results. Data gaps include no secondary-hazards data for difethialone and few for bromethalin and cholecalciferol. For difethialone, which is highly similar to brodifacoum but used at a lower ai in baits (50 ppm vs 25 ppm), an assumption is made that secondary mortality would be about 80% of that reported for brodifacoum. Data are sufficient to distinguish differences in potential primary risks between 50 ppm and 100 ppm chlorophacinone and diphacinone baits but are insufficient to assess differences in secondary risks. Also, few if any data are available regarding retention time in blood and/or liver for some rodenticides, especially first-generation anticoagulants and the non-anticoagulants.

The incident data are not included in the comparative analysis model results but are meaningful for characterizing risk. A comparison of incidents versus the summary risk values for each rodenticide bait is depicted in Figure 9 (see graphs 9 and 10 in Attachment C for separate plots for birds and mammals). The baits with the most incidents and highest risk values are in the upper left, whereas those with the fewest incidents and lowest risk values are in the lower right portion of the graph. Brodifacoum is distinguished by its high summary value and high number of incidents in relation to the other rodenticides. Distinctions cannot be made between the 50 ppm and 100 ppm chlorophacinone and diphacinone baits in the incident data, but the 100 ppm baits are likely to present greater risk than the 50 ppm baits.

Figure 9. Plot of Summary Risk Values Versus Number of Incidents For Each Rodenticide



A “lines-of-evidence” assessment was performed based on the available data and supporting information. Each rodenticide is assigned a rating of high, moderate, or low for primary risk to birds, primary risk to nontarget mammals, secondary risk to birds, and secondary risk to mammals (Table 49). Differences among the rodenticides in their potential primary and secondary risks to birds are pronounced. Brodifacoum, and possibly difethialone, baits present the highest potential overall primary and secondary risks to birds and nontarget mammals. Brodifacoum is hazardous to birds and mammals, is persistent, and is widely used for commensal rodent control (see Table 2 for over-the-counter sales in 1996 and 1997). Difethialone is also hazardous to birds and mammals and it is very similar to brodifacoum (e.g., chemical structure, acute-toxicity profile). However, some uncertainty exists when comparing difethialone risks to brodifacoum risks, because market-share and use information and secondary-hazards data are lacking.

Based on the lines-of-evidence assessment, potential primary risks to birds are highest for zinc phosphide, brodifacoum, and difethialone. A small bird finding and eating a pellet or two of any of these baits is likely to ingest a lethal dose, and just a few pellets could provide a lethal dose to larger birds. In contrast, it seems highly unlikely that any small bird could eat 100 to 1000 pellets in a single feeding, which would be needed to provide an LD50 dose from a first-generation anticoagulant, bromadiolone, or cholecalciferol bait. Avian dietary RQs for zinc phosphide, brodifacoum, and difethialone greatly exceed the Agency’s LOC for acute risk to birds, whereas they are not or only slightly exceeded for other rodenticides. The dietary RQ provides some useful information for comparing potential risks among rodenticide baits but is based on birds feeding continuously on rodenticide bait for several days. Although some birds might do so, others might only find one or a few pellets in a foraging bout. Therefore, the number of pellets needed to be eaten to provide an LD50 dose may be a more appropriate approximation of potential risk than is the dietary RQ. Nevertheless, the characterization of risk does not change based on the method used to estimate potential risk.

Brodifacoum and difethialone clearly present a greater potential risk to raptors and avian scavengers than do the other rodenticides. Risks posed by brodifacoum are apparent from experimental and other control applications in outdoor settings and from many incidents involving owls, hawks, eagles, corvids and other birds. Concern about risks of second-generation anticoagulants to avian predators and scavengers is widely expressed in the rodenticide literature (Colvin et al. 1988; Hegdal and Colvin 1988; Joermann 1998; Howald et al. 1999; Stephenson et al. 1999; Stone et al. 1999), and the need to monitor residues and population trends is evident (Newton et al. 1990, 1999). This need is especially critical for brodifacoum, because it is so widely used for commensal-rodent control and because it may pose a greater potential risk compared to the other rodenticides.

Rodenticide baits are not selective to the target species. Some baits pose a greater hazard than others, but all rodenticides pose a risk to small nontarget mammals that eat bait, and many pose a potential risk to mammals that prey or scavenge dead or dying rodents that have eaten bait. Baits are formulated to be lethal to small mammals, and many small nontarget mammals are likely to find and eat bait available around the outside of buildings, inside barns and farm or utility shed, or in other outdoor settings.

Table 49. Primary and Secondary Risk Presumptions For Birds and Nontarget Mammals

Rodenticide	Primary risks		Secondary risks	
	birds	mammals	birds	mammals
Second-generation anticoagulants				
Brodifacoum	high	high	high	high
Difethialone	high	high	high	high
Bromadiolone	low to moderate	high	moderate	high
First-generation anticoagulants				
Diphacinone	low	high	moderate	high
Chlorophacinone	low to moderate	high	low	high
Warfarin	low	high	low	moderate
Others (non-anticoagulants)				
Bromethalin	moderate to high	high	insufficient data available	
Zinc phosphide	high	high	low	low
Cholecalciferol	low to moderate	high	insufficient data available	

The anticoagulants present a potential secondary risk to mammals, although warfarin probably to a lesser extent than the others. The incident data in Attachment D helps characterize and corroborate these risks. Zinc phosphide potentially poses minimal risks to either predatory birds or mammals, but insufficient data are available for bromethalin and cholecalciferol.

Eason et al. (2001) assessed risks of brodifacoum to nontarget birds and mammals in New Zealand, where brodifacoum is widely used to control rodents and possums. They conclude that ". . . the recorded mortality of birds after some control operations, coupled with the detection of brodifacoum residues in a range of wildlife including native birds and feral game animals raises serious concerns about the long-term effects of the targeted field use of brodifacoum or its use around farms where wildlife might encounter poisoned carcasses." Eason et al. (in prep.) also note: "On an international level we note that the reports of non-target wildlife mortality and contamination in raptors and mustelids from anticoagulants are on the increase (Shore *et al.*, 1999; Howald *et al.* 1999; Stone *et al.* 1999; B. Hosea, pers. comm.) and we strongly recommend that residue-monitoring programmes are established in those countries where anticoagulants are used in the field or extensively around farm buildings. An improved understanding of the risk associated with this class of compound will be achieved when there is a better understanding of whether or not food-chain contamination is occurring. The development of 'biomarkers' of exposure for different bird species will assist those agencies involved in wildlife protection."

More information also is needed on the potential adverse sublethal effects of rodenticides. Newton et al. (1990) note that ". . . there remains the possibility that sub-lethal levels of rodenticide may predispose death from other causes, or reduce the chance of recovery from accidents." Eason and Murphy (2001) emphasize that the risk of brodifacoum is magnified by its persistence, which could lead to accumulation on repeated exposure. A compound that is rapidly metabolized or excreted from a primary consumer may result in a lesser risk than one that bioaccumulates with repeated sublethal exposure, even if repeated exposure occurs weeks or even months after the initial exposure. Those compounds more rapidly cleared from the body are less likely to pose such long-term risk. Unfortunately, most laboratory tests and risk assessments do not consider the potential for bioaccumulation of the highly persistent anticoagulant compounds. Sublethal effects on reproduction will be considered when the data become available.

Uncertainty and Data Needs

A number of factors contribute uncertainty to the assessment. Those that appear to contribute the greatest uncertainty are: (1) missing data, including acute, chronic, and secondary toxicity as well as retention of some active ingredients in the liver, blood, and other body tissues; (2) the variable quality and quantity of existing data on metabolism and retention times in rodents and nontarget species; (3) specific use information by formulation, including typical amounts applied by use site, seasonally, and annually; distances applied from buildings; amounts used in rural versus urban areas; use by Certified Applicators versus homeowners and other non-certified applicators; and other such relevant information; (4) information on the number and species of birds and nontarget mammals frequenting baited areas and their likelihood of their finding and consuming bait or poisoned primary consumers in the various use areas; (5) methods to determine liver concentration(s) and total body burdens of rodenticide that would corroborate death or even if such a cause-effect relationship is appropriate (e.g., the "threshold of toxicity" concentration); (6) not accounting for the impacts of sublethal effects on reproduction and nontarget mortality (e.g., clotting abnormalities, hemorrhaging, stress factors including environmental stressors, such as adverse weather conditions, food shortages, and predation); (7) not accounting for bioaccumulation of repeated sublethal exposures to bait or poisoned rodents utilized as food by predators and scavengers; and (8) lack of incident reporting.

The greatest reduction in uncertainty for these analyses is likely to come from addressing data gaps where data is missing or needs to be standardized because quality is variable, as well as obtaining specific use and exposure information. Some of the concerns about adverse sublethal effects can be addressed through reproduction studies, which the Agency will require for all pesticides with outdoor uses. The no-observable-adverse-effects concentration (NOAEC) established from these studies will be a more appropriate indicator of a toxicity threshold than is the liver residue in dead animals.

Endangered Species Considerations

In response to a formal consultation requested by EPA (1991b) under Section 7 of the Endangered Species Act, the United States Fish and Wildlife Service issued a Biological Opinion on *Effects of 16 Vertebrate Control Agents On Threatened and Endangered Species* in March, 1993 (USFWS 1993). The Biological Opinion included jeopardy determinations for mammals, birds, and reptiles potentially exposed via primary or secondary exposure to brodifacoum, bromadiolone, chlorophacinone, diphacinone, warfarin, bromethalin, zinc phosphide, and cholecalciferol. For each species addressed in the Biological Opinion, the Service determined either that use of the rodenticide "is likely to jeopardize" or "is not likely to jeopardize" the continued existence of the species. For the likely-to-jeopardize determinations the Service provided "reasonable and prudent alternatives" that preclude jeopardy but still allow use of the rodenticide. These alternatives represent the Service’s best professional judgement of the measures necessary to provide the appropriate level of protection to the species. The Service also provided "incidental take" statements and "reasonable and prudent measures" to minimize take. Table 50 indicates the number of species, by rodenticide, for which the Service made a likely-to-jeopardize determination. The species addressed, jeopardy and no-jeopardy determinations, and the Service’s reasonable and prudent alternatives and/or measures are tabulated for each of the 8 rodenticides in Attachment E. Difethialone, first registered in 1995, is not addressed in this or any subsequent Biological Opinion, but EPA believes the jeopardy determinations for brodifacoum also would be applicable for difethialone.

Table 50. USFWS (1993) Jeopardy Determinations For Endangered and Threatened Species at Risk From Use of Each Rodenticide (Except Difethialone).

Rodenticide	no. species likely at jeopardy		
	mammals	birds	reptiles
Brodifacoum	10	2	0
Bromadiolone	7	0	0
Chlorophacinone	20	1	0
Diphacinone	28	1	0
Warfarin	10	0	0
Bromethalin	10	0	0
Zinc phosphide	16	9	0
Cholecalciferol	10	0	0
Total no. species	29	11	0

Acknowledgments

We would like to thank those people who took the time and effort to provide information, critical peer review, or comments on various drafts of this assessment. We are especially grateful to C. Eason (Centre for Environmental Toxicology, New Zealand), E. Hill (USGS Patuxent Wildlife Research Center, retired), and R. O'Connor (University of Maine) for critical peer review of a previous draft of this assessment. Their peer reviews and credentials as peer reviewers are available in the public docket for the rodenticides. Dr. Eason also generously provided data from his research with rodenticides, especially brodifacoum and cholecalciferol, in New Zealand. Thanks also to G. Joermann (Federal Biological Research Centre for Agriculture and Forestry, Germany) and B. Rattner (USGS Patuxent Wildlife Research Center) for providing constructive comments and information. Other scientists who commented on previous drafts or various relevant topics include:

T. Bargar, EPA Office of Pesticides Program
S. Bradbury, EPA Office of Pesticides Program
J. Brooks, Tetrahedron, Inc.
S. Cragg, Tetrahedron, Inc.
C. Cubbison, EPA Office of Research and Development
J. Goodyear, EPA Office of Pesticides Program
G. Howald, Island Conservation and Ecology Group
W. Jacobs, EPA Office of Pesticides Program
N. Mastrota, EPA Office of Pesticides Program
P. Mineau, Canadian Wildlife Service
C. Moulton, Tetrahedron, Inc.
D. Rieder, EPA Office of Pesticides Program
T. Sinnott, NY State Department of Environmental Conservation

R. Hosea (California Department of Fish and Game) and W. Stone (NY State Department of Environmental Conservation) have provided most of the incident data cited in the assessment. The Wisconsin Department of Natural Resources also submitted several incident reports. The National Wildlife Health Center in Madison, WI generously provided data from their database, even though their primary focus is wildlife diseases. The Predatory Bird Research Group (University of California, Santa Cruz) furnished background and clinical histories of the three golden eagles from Santa Cruz Island, and N. Hamlett (Harvey Mudd College) contributed information on nontarget mortality and brodifacoum poisoning of owls and a hawk in Claremont, CA. The cooperation of these individuals and organizations is greatly appreciated.

T. Nguyen (EPA Office of Pesticides Program) drew most of the chemical structures in Attachment A.
K. McCormack (EPA Office of Pesticides Program) provided editorial comments.

W. Erickson would also like to acknowledge the input of Doug Urban in conducting this assessment. Doug passed away in December of 2003. He will be missed.

Attachment A: Chemical Structures and Selected Physical/Chemical Properties of the Rodenticides

Brodifacoum:

Chemical name:	3-[3-(4'-bromo[1,1'-biphenyl]-4-yl)-1,2,3,4-tetrahydro-1-naphthalenyl]-4-hydroxy-2H-1-benzopyran-2-one
Chemical structure:	Class:	coumarin anticoagulant
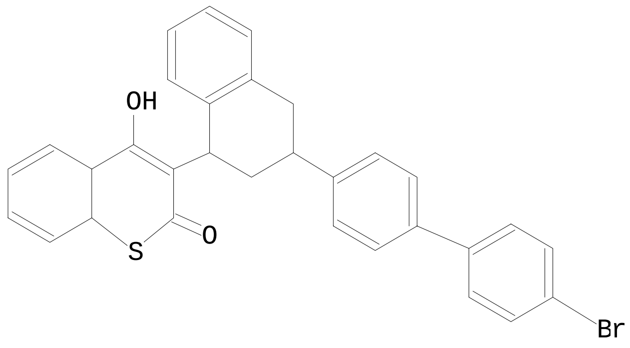
Molecular formula:	$C_{31}H_{23}BrO_3$
Molecular weight:	523.4
Physical state:	solid
Melting point:	228-232º C
Solubility:	<10 ppm in water at 20º C, pH 7

Difethialone:

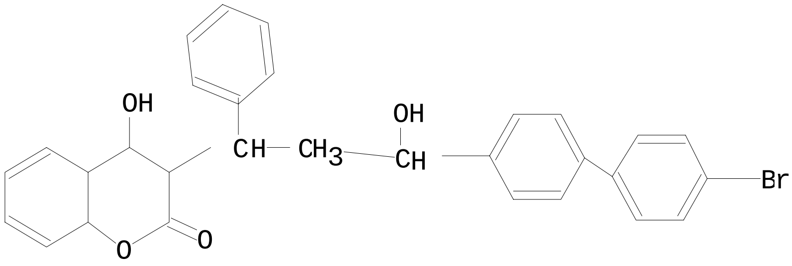
Chemical name:	3-[3-(4'-bromo[1,1'-biphenyl]-4-yl)-1,2,3,4-tetrahydro-1-naphthalenyl]-4-hydroxy-
Chemical structure:	



Class:	coumarin anticoagulant
Molecular formula:	$C_{31}H_{24}BrO_2S$
Molecular weight:	539.5
Physical state:	solid
Melting point:	230° C
Solubility:	0.39 ppm in water at 25° C

Bromadiolone:

Chemical name:	3-[3-(4'-bromo[1,1'-biphenyl]-3-hydroxy-1-phenylpropyl]-4-hydroxy-2H-1-benzopyrane-2-one
Chemical structure:	

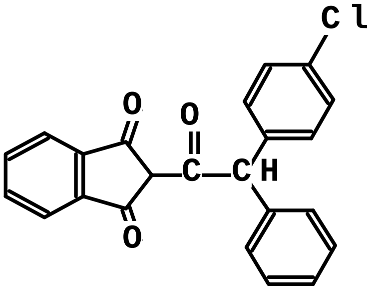


Class:	coumarin anticoagulant
Molecular formula:	$C_{30}H_{23}BrO_4$
Molecular weight:	527.4
Physical state:	solid
Melting point:	200-210° C
Solubility:	12 ppm in water at 20° C

Chlorophacinone:

Chemical name: 2-[(4-chlorophenyl)phenylacetyl]-1H-indene-1,3(2H)-dione

Chemical structure:



Class: indandione anticoagulant

Molecular formula: $C_{23}H_{14}O_3Cl$

Molecular weight: 373.8

Physical state: solid

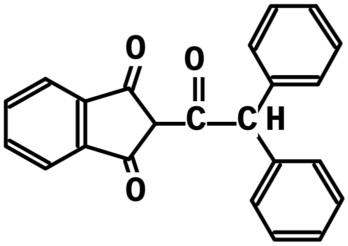
Melting point: 140° C

Solubility: 20-34 ppm

Diphacinone:

Chemical name: 2-(diphenylacetyl]-1H-indene-1,3(2H)-dione

Chemical structure:



Class: indandione anticoagulant

Molecular formula: $C_{23}H_{16}O_3$

Molecular weight: 340.4

Physical state: solid

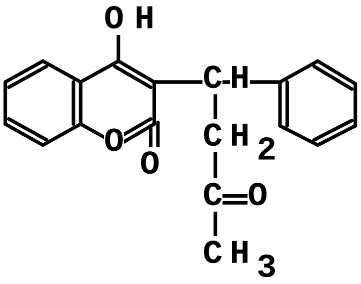
Melting point: 141-145^o C

Solubility: 17-30 ppm in water (not verified)

Warfarin:

Chemical name: 4-hydroxy-3-(3-oxo-1-phenylbutyl)-2H-1-benzopyran-2-one

Chemical structure:

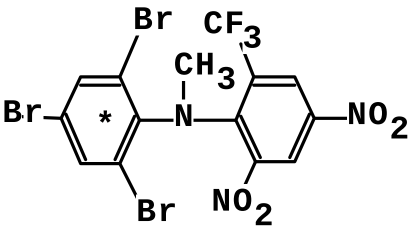


Class:	coumarin anticoagulant
Molecular formula:	$C_{19}H_{16}O_4$ $C_{19}H_{15}NaO_4$ (sodium salt)
Molecular weight:	308.4 330.1 (sodium salt)
Physical state:	solid
Melting point:	159-165^o C
Solubility:	0.196 ppm in water at 25^o C

Bromethalin:

Chemical name: N-methyl-2,4-dinitro-N-(2,4,6-tribromophenyl)-6-(trifluoromethyl)-benzenamine

Chemical structure:



Class: diphenylamine

Molecular formula: $C_{13}H_7Br_3F_3N_3O_4$

Molecular weight: 578.0

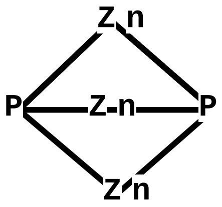
Physical state: solid

Melting point: 148-152°C

Solubility: 3.8 ppb at 25°C

Zinc phosphide:

Chemical name:	zinc phosphide
Chemical structure:	

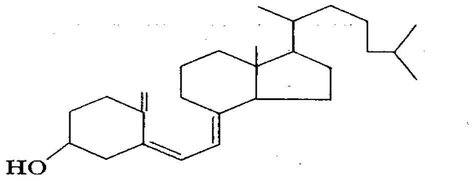


Class:	inorganic compound
Molecular formula:	Zn_3P_2
Molecular weight:	258.09
Physical state:	solid
Melting point:	420° C
Solubility:	reported to be insoluble in water

Cholecalciferol:

Chemical name: 9,10-Secocholesta-5,7,10(19)-trien-3 beta-ol

Chemical structure:



Class: sterol

Molecular formula: $C_{27}H_{44}O$

Molecular weight: 384.6

Physical state: solid

Melting point: 84-85° C

Solubility: no data available, but reported to be insoluble in water

Attachment B: Common and Scientific Names of the Birds and Mammals Cited in the Assessment

Order/ Common name	Scientific name	Family
Waterfowl (Anseriformes)		
Mallard	*Anas platyrhynchos*	Anatidae
Canada goose	*Branta canadensis*	Anatidae
White-fronted goose	*Anser albifrons*	Anatidae
Snow goose	*Chen caerulescens*	Anatidae
Paradise shelduck	*Tadorna variegata*	Anatidae
Grey duck	*Anas superciliosa*	Anatidae
Gallinaceous birds (Galliformes)		
Northern bobwhite	*Colinus virginianus*	Phasianidae
Ring-necked pheasant	*Phasianus colchicus*	Phasianidae
California quail	*Callipepla californica*	Phasianidae
Japanese quail	*Coturnix coturnix*	Phasianidae
Chukar	*Alectoris chukar*	Phasianidae
Gray partridge	*Perdix perdix*	Phasianidae
Turkey (wild)	*Meleagris gallopavo*	Phasianidae
Owls (Strigiformes)		
Barn owl	*Tyto alba*	Tytonidae
Great-horned owl	*Bubo virginianus*	Strigidae
Spotted eagle owl	*Bubo africanus*	Strigidae
Northern saw-whet owl	*Aegolius acadicus*	Strigidae
Eastern screech-owl	*Otus asio*	Strigidae
Long-eared owl	*Asio otus*	Strigidae
Short-eared owl	*Asio flammeus*	Strigidae
Spotted owl	*Strix occidentalis*	Strigidae
Tawny owl	*Strix aluco*	Strigidae
Barred owl	*Strix varia*	Strigidae
Snowy owl	*Nyctea scandiaca*	Strigidae
Morepork	*Ninox novaeseelandiae*	Strigidae

Order/ Common name	Scientific name	Family
Diurnal birds of prey (Falconiformes)		
Red-tailed hawk	*Buteo jamaicensis*	Accipitridae
Red-shouldered hawk	*Buteo lineatus*	Accipitridae
Eurasian buzzard	*Buteo buteo*	Accipitridae
Broad-winged hawk	*Buteo platypterus*	Accipitridae
Rough-legged hawk	*Buteo lagopus*	Accipitridae
Cooper's hawk	*Accipiter cooperii*	Accipitridae
Sharp-shinned hawk	*Accipiter striatus*	Accipitridae
Northern goshawk	*Accipiter gentilis*	Accipitridae
Golden eagle	*Aquila chrysactos*	Accipitridae
Bald eagle	*Haliaeetus leucocephalus*	Accipitridae
Eurasian harrier	*Circus pygargus*	Accipitridae
Australasian harrier	*Circus approximans*	Accipitridae
Kite	*Milvus migrans*	Accipitridae
American kestrel	*Falco sparverius*	Falconidae
Merlin	*Falso columbarius*	Falconidae
Peregrine falcon	*Falco peregrinus*	Falconidae
New Zealand falcon	*Falco novaeseelandiae*	Falconidae
Turkey vulture	*Cathartes aura*	Cathartidae
Black vulture	*Coragyps atratus*	Cathartidae
Herons (Ciconiformes)		
Great blue heron	*Ardea herodias*	Ardeidae
White stork	*Ciconia ciconia*	Ciconiidae
Gulls and shorebirds (Charadriiformes)		
Southern black-backed gull	*Larus dominicans*	Laridae
Laughing gull	*Larus atricilla*	Laridae
Black-billed gull	*Larus bulleri*	Laridae
Franklin's gull	*Larus pipixcan*	Laridae
Brown skua	*Catharacta skua*	Stercorariidae
New Zealand dotterel	*Charadrius obscurus*	Charadriidae
Variable oystercatcher	*Haematopus unicolor*	Haematopodidae

Order/ Common name	Scientific name	Family
Rails (Gruiformes)		
Weka	*Gallirallus australus*	Rallidae
Pukeko (purple gallinule)	*Porphyrio porphyrio*	Rallidae
Spotless crake	*Porzana tabuensis*	Rallidae
Parrots (Psittaciformes)		
Kaka	*Nestor meridionalis*	Psittacidae
Kakariki	*Cyanoramphus* sp.	Psittacidae
Pigeons/doves (Columbiformes)		
Mourning dove	*Zenaida macroura*	Columbidae
Kereru	*Hemiphaga novaeseelandiae*	Columbidae
Kiwi (Apterygiformes)		
Brown kiwi	*Apteryx mantelli*	Apterygidae
Perching Birds (Passeriformes)		
American crow	*Corvus brachyrhynchos*	Corvidae
Carrion crow	*Corvus corone*	Corvidae
Common raven	*Corvus corax*	Corvidae
Northwestern crow	*Corvus caurinus*	Corvidae
Fish crow	*Corvus ossifragus*	Corvidae
Black-billed magpie	*Pica pica*	Corvidae
Blue jay	*Cyanocitta cristata*	Corvidae
Australian magpie	*Gymnorhina tibicen*	Cracticidae
Myna	*Acridotheres tristis*	Sturnidae
House sparrow	*Passer domesticus*	Passeridae
Horned lark	*Eremophila alpestris*	Alaudidae
Lincoln’s sparrow	*Melospiza lincolnii*	Emberizidae
Song sparrow	*Melospiza melodia*	Emberizidae
Red-winged blackbird	*Agelaius phoeniceus*	Emberizidae
Canary	*Serinus canarius*	
Chaffinch	*Fringilla coelebs*	Fringillidae
Robin (New Zealand)	*Petroica australis*	Eopsalttriidae

Order/ Common name	Scientific name	Family
Tomtit	*Petroica macrocephala*	Eopsalttriidae
Fantail	*Rhipidura fuliginosa*	Monarchidae
Bellbird	*Anthornis melanura*	Meliphagide
Tui	*Prosthemadera novaeseelandiae*	Meliphagide
Saddleback	*Philesturnus carunculatus*	Callaeidae
Kokako	*Callaeas cinerea*	Callaeidae
Whitehead	*Mohoua ochrocephala*	Pachycephalidae
Silvereye	*Zosterops lateralis*	Zosteropidae
Blackbird (Eurasian)	*Turdus merula*	Muscicapidae
Rodents (Rodentia)		
Norway rat	*Rattus norvegicus*	Muridae
Roof rat (black rat, ship rat)	*Rattus rattus*	Muridae
Polynesian rat	*Rattus exulans*	Muridae
House mouse	*Mus musculus*	Muridae
Deer mouse	*Peromyscus maniculatus*	Muridae
Meadow vole	*Microtus pennsylvanicus*	Muridae
Pine vole	*Microtus pinetorum*	Muridae
Water vole	*Arvicola terrestris*	Muridae
Muskrat	*Ondatra zibethicus*	Muridae
Heermann’s kangaroo rat	*Dipodomys heermanni*	Heteromyidae
Banner-tailed kangaroo rat	*Dipodomys spectabilis*	Heteromyidae
San Joaquin pocket mouse	*Perognathus inornatus*	Heteromyidae
Botta’s pocket gopher	*Thomomys bottae*	Geomyidae
California ground squirrel	*Spermophilus beecheyi*	Sciuridae
Richardson’s ground squirrel	*Spermophilus richardsonii*	Sciuridae
Rock squirrel	*Spermophilus variegatus*	Sciuridae
Black-tailed prairie dog	*Cynomys ludovicianus*	Sciuridae
Gray squirrel	*Sciurus carolinensis*	Sciuridae
Fox squirrel	*Sciurus niger*	Sciuridae
Eastern chipmunk	*Tamias striatus*	Sciuridae

Order/ Common name	Scientific name	Family
Nutria (coypu)	*Myocastor coypus*	Myocastoridae
Insectivores (Insectivora)		
Dusky shrew (montane shrew)	*Sorex monticolus*	Soricidae
Rabbits/hares (Lagomorpha)		
Cottontail rabbit	*Sylvilagus floridanus*	Leporidae
Desert cottontail	*Sylvilagus auduboni*	Leporidae
Black-tailed jack rabbit	*Lepus californicus*	Leporidae
European rabbit	*Oryctolagus cuniculus*	Leporidae
European hare	*Lepus capensis*	Leporidae
Carnivores (Carnivora)		
Coyote	*Canis latrans*	Canidae
Red fox	*Vulpes vulpes*	Canidae
San Joaquin kit fox	*Vulpes macrotis mutica*	Canidae
Gray fox	*Urocyon cinereoargenteus*	Canidae
Mountain lion	*Felis concolor*	Felidae
Bobcat	*Lynx rufus*	Felidae
Lynx	*Lynx lynx*	Felidae
Badger	*Meles meles*	Mustelidae
Ermine (stoat)	*Mustela erminea*	Mustelidae
European ferret	*Mustela putorius furo*	Mustelidae
Siberian ferret	*Mustela eversmanni*	Mustelidae
Mink	*Mustela vison*	Mustelidae
Least weasel	*Mustela nivalis*	Mustelidae
Long-tailed weasel	*Mustela frenata*	Mustelidae
Polecat	*Mustela putorius*	Mustelidae
Striped skunk	*Mephitis mephitis*	Mustelidae
Stone marten	*Martes foina*	Mustelidae
Raccoon	*Procyon lotor*	Procyonidae
Mongoose	*Herpestes auropunctatus*	Herpestidae

Order/ Common name	Scientific name	Family
Marsupials (Marsupialia)		
Opossum	*Didelphis virginiana*	Didelphidae
Brushtail possum	*Trichosurus vulpecula*	Phalangeridae
Ungulates (Artiodactyla)		
White-tailed deer	*Odocoileus virginianus*	Cervidae
Roe deer	*Capreolus capreolus*	Cervidae
Boar (pig)	*Sus scrofa*	Suidae

Attachment C: Comparing Potential Risks of Rodenticide Baits to Birds and Mammals Using A Comparative Analysis Model

Prepared by: Douglas J. Urban, Senior Scientist, EFED

Executive Summary

The standard comparative analysis modeling technique often used in decision-analysis called the simple multi-attribute rating technique or SMART is adapted for comparing the risks of rodenticide baits based on a number of measures of effect values for primary and secondary risk to birds and mammals. Of the 11 rodenticide baits considered in the main document, three are considered to pose the greatest overall potential risk to birds and mammals: brodifacoum, zinc phosphide, and difethialone. Based on this analysis, brodifacoum poses the greatest potential risk to birds and mammals, and by a substantial margin over the other rodenticide baits. Brodifacoum has higher summary risk values than zinc phosphide for both secondary risk to birds and secondary risk to mammals. Zinc phosphide has higher summary risk values than difethialone for both primary risk to birds and primary risk to mammals.

A sensitivity analysis is performed to identify the most sensitive measure of effect(s) and to determine if changes of 50% or more in these sensitive measures of effect would change the results of the analysis. The results of this analysis show that the ranking for the rodenticide baits which pose the greatest potential risk to birds and mammals is robust when the measures of effect are changed by +/- 50%. The ranking is generally robust when the measures of effect are changed by +/- 99%, with the following exceptions: a reduction of greater than 67% in the Mean Dietary Risk Quotient for brodifacoum, 64% in the Mean (%) Mortality of Secondary Lab Studies on Birds for brodifacoum, and 76% in the Mean (%) Mortality of Secondary Lab Studies on Mammals for brodifacoum, would result in zinc phosphide moving ahead of brodifacoum as posing the greatest overall risk to birds and mammals; and, an increase of 99% in the Mean (%) Mortality of Secondary Lab Studies on Mammals for difethialone would result in difethialone moving ahead of zinc phosphide as posing the second greatest overall risk to birds and mammals. Thus, with few exceptions, the sensitivity analysis shows that brodifacoum poses the greatest overall potential risk to birds and mammals, followed by zinc phosphide and difethialone.

Acute toxicity reference values for rodenticides to birds and an alternative approach are also considered. The toxicity reference values from a recent publication are substituted for the avian LD50 values for bobwhite quail and mallard ducks used in one of the avian measures of effect for Primary Risk to Birds. The results show that the overall ranking remains the same and the use of these toxicity values does not affect the analysis. When unequal weighting of measures of effect for each type of risk is ignored and all measures of effect are considered together, again the results show that the overall ranking does not change. Unequal weighting of one type of risk over another, at least in this case, does not appear to have a significant effect on the overall ranking.

Two factors are identified as contributing the greatest uncertainty to the analysis: (1) missing data, especially secondary mortality data for difethialone, bromethalin, and cholecalciferol, and blood and liver retention values for a number of rodenticides; and (2) the assumption that field mortality to birds and mammals due to difethialone would likely equal 80% of that reported for brodifacoum. This assumption is based on the many chemical similarities between these two rodenticides, because difethialone bait is formulated at a lower % a.i. than brodifacoum, and the fact that compared to brodifacoum less difethialone is used.

The available incidents for birds and mammals are analyzed and compared to the summary of the weighted average risk values. The results confirm that brodifacoum is the rodenticide bait that poses the greatest potential overall risk to birds and mammals, but they also identify bromadiolone and zinc phosphide as potential concerns for birds, and bromadiolone, diphacinone (100 ppm), and chlorophacinone (100 ppm) as potential concerns for mammals.

Introduction

Comparative risk assessment can be a daunting process when risk assessors are faced with risks for a number of alternative pesticides covering multiple endpoints. When attempting to decide which pesticides present the greatest overall risk and having to consider many different endpoints that lead to a matrix of comparisons, many risk assessors rely on individual or group intuition. The inability to simultaneously track risk values assigned to multiple endpoints among many alternative pesticides as well as the varying importance of each to the assessment can easily result in paralysis (indecision).

The Agency attempted to address such situations in a December 1998 presentation to the Federal Insecticide, Fungicide and Rodenticide (FIFRA) Science Advisory Panel (SAP) titled, "*A Comparative Analysis of Ecological Risks from Pesticides and Their Use: Background, Methodology, Case Study*"[1]. The Panel noted the many scientific uncertainties in the method, yet agreed that it was a useful screening tool that provides a rough estimate of relative risk. The Panel also made a number of helpful suggestions to improve the utility of the methodology presented for use in comparative analyses of ecological risk from pesticides. There are, however, two recommendations that the panel thought critical for valid results: risk quotients - risk indices which are used to express risk from pesticides to nontarget organisms, should never be combined (added); and, a sensitivity analysis should always be included. Following this advice, no risk quotients or indices have been added together for this analysis, and a sensitivity analysis has been included. An early draft of this analysis was submitted for additional peer review by experts outside the Agency. Their comments and suggestions are very helpful and have also been incorporated, to the extent possible, into the updated analysis and this final report.

Endpoint and Data Selection

This comparative analysis of the potential risks from eleven rodenticide baits is based on the available primary and secondary toxicity data and persistence information for the nine rodenticides which are presented the main document *"Potential Risks of Nine Rodenticides to Birds and Nontarget Mammals: A Comparative Approach"*. Henceforth, this will be referred to as the "main document". These eleven baits are compared based on four types of risk: primary risk to birds, primary risk to mammals, secondary risk to birds, and secondary risk to mammals. Each type of risk is quantitatively evaluated by one to three measures of effect:

Type or Risk	Measures of Effect (ME)
Primary Risk to Birds	1) Mean Dietary Risk Quotient (RQ = the ppm ai in the rodenticide bait/LC50). See Table 29 in the main document. When more than one dietary RQ is available, the mean is calculated and used.
	2) Inverse of the No. of Bait Pellets Needed for 100-g Bird to Ingest LD50 Dose at a Single Feeding See Table 28 in the main document and the 'no. bait pellets' column under 100-g non-passerine. All > values are assumed to be = values.
Primary Risk to Mammals	1) Inverse of the No. of Bait Pellets Needed for 100-g Mammal to Ingest LD50 Dose at a Single Feeding See Table 31 in the main document and the 'no. bait pellets' column under 100-g rodent. All > values are assumed to be = values.
Secondary Risk to Birds	1) Mean % Mortality of Secondary Lab Studies (Birds). See Tables 11-12, 14-16, 18-19 in the main document and the '% dead' column. Missing data are not considered in the analysis. Difethialone is considered a special case due to it's similarity to brodifacoum. While missing data, it is given a % equal to 80% of that for brodifacoum. Bait specific data is not available; thus, where there are two baits (chlorophacinone, diphacinone), the % dead is applied to both baits. 2) Blood Retention Time (days). See Tables 13 and 17 in the main document and the 'Blood $t_{1/2}$' column. Missing data are not considered in the analysis. Where multiple half-lives existed, the mean is calculated and used. Bait specific data are not available; thus, where there are two

	baits (chlorophacinone, diphacinone), the half-life is applied to both baits.
	3) Liver retention Time (days). See Tables 13 and 17 in the main document and the ‘Liver $t_{1/2}$‘ column. Missing data are not considered in the analysis. Where multiple half-lives existed, the mean is calculated and used. Bait specific data is not available; thus, where there are two baits (chlorophacinone, diphacinone), the half-life is applied to both baits.
Secondary Risk to Mammals	1) Mean % Mortality of Secondary Lab Studies (Mammals). See Tables 20-27 in the main document and the ‘% dead’ column. Missing data are not considered in the analysis. Difethialone is considered a special case due to it’s similarity to brodifacoum. It is given a % equal to 80% of that for brodifacoum. Bait specific data is not available; thus, where there are two baits (chlorophacinone, diphacinone), the % dead is applied to both baits.
	2) Blood Retention Time (days). See Tables 13 and 17 in the main document and the ‘Blood $t_{1/2}$‘ column. Missing data are not considered in the analysis. Where multiple half-lives existed, the mean is calculated and used. Bait specific data is not available; thus, where there are two baits (chlorophacinone, diphacinone), the half-life is applied to both baits.
	3) Liver retention Time (days). See Tables 13 and 17 in the main document and the ‘Liver $t_{1/2}$‘ column. Missing data are not considered in the analysis. Where multiple half-lives existed, the mean is calculated and used. Bait specific data is not available; thus, where there are two baits (chlorophacinone, diphacinone), the half-life is applied to both baits.

Table 1 contains the data for each of the measures of effect used in the analysis.

Method & Approach[2]

---

[2] Much of the software description is based on a software review by Len Tashman and Sara Munro, 1997.

During the 1998 SAP presentation, commercially available software called *DecideRight® (Version 1.2)*[3] was presented as an useful tool designed to aid comparative analysis and support decision-making. This user friendly software is designed primarily for use in business, but it can be applied to many situations where risk assessors and decision-makers must choose among alternatives when many factors must be considered. The underlying methodology used in the software is called the simple multi-attribute rating technique or SMART (Goodwin and Wright, 1998). This technique was developed approximately 30-years ago and has become a standard in decision modeling. When faced with a number of alternatives pesticide baits and a number of types of risk with measures of effect, SMART prescribes that (1) each alternative pesticide be rated on each measure of effect, (2) each measure of effect be assigned a measure of importance to the decision-maker, and (3) a summary score for each alternative pesticide be calculated as a weighted average of the ratings, where the weights represent the relative importance of the measure of effect for each type of potential risk. In the end, the higher the summary score, the higher the potential risk for that alternative pesticide. The result of this process has proved to be superior to the alternative of reliance on intuition.

SMART is not rooted in probability and ignores any interaction or correlation between criteria. The assigned ratings are assumed to be based on full knowledge of the type of risk. However, some uncertainty can be dealt with in the ratings by a sensitivity analysis. In this case, two scenarios are developed where the individual risk ratings are varied to see the effect on the overall ranking. This results of this analysis is included.

To begin, the problem must be formulated as a question. In this analysis, the question being asked is: "*Which of the 11 Rodenticide Baits Pose the Greatest Overall Risk to Birds and Mammals Based on their Primary and Secondary Risk Characteristics?*" The following basic equation is used to calculate the summary values for the risk comparison:

Equation 1.

$$\textbf{Summary Value}_{\text{(scale from 0 to 10)}} = \Sigma\,[(\mathbf{ME}_i)(\mathbf{ME}_{max})^{-1}]\,[(\mathbf{Weight})\,(\Sigma\mathbf{Weights})^{-1}]\,(10)$$

where $\mathbf{ME}_i$ is the measure of effect value for one of the eleven rodenticide baits and $\mathbf{ME}_{max}$ is the maximum ME for all rodenticide baits; **Weight** is the importance value placed on each measure of effect, with high = 10 to 6.67, medium = 6.68 to 3.33, and low = 3.34 to 0; and, Σ**Weights** is the sum of all the weights for all the measures of effect.

For this analysis, potential risk increased as all measures of effect values increased. For two measures: No. Bait Pellets Needed for 100-g Bird to Ingest LD50 Dose at a Single Feeding; and,

---

[3] *DecideRight®* was developed by Avantos Performance Systems of Emertville, California. The company has since closed; however, the software is still available from Performance Management Solutions, LLC, 1198 Pacific Coast Hwy., D515 Seal Beach, CA. 90740 [Ph. 562/430-7096 Ext. 0 - Fax. 800/645-6618]. Also, see http://www.performancesolutionstech.com/default.htm . Mention of this commercial product does not constitute a recommendation or endorsement by EPA.

No. Bait Pellets Needed for 100-g Mammal to Ingest LD50 Dose at a Single Feeding, the inverse of the number of bait pellets was used in order to correctly calculate the weighted averages and avoid skewed results. Further, the weights given to all measures of effect are high (=10) since we did not have any scientific reason to differentiate between the importance of the measures, except for the two measures of retention or persistence in prey. The half-life in blood and liver are each given a weight of medium (2.5) for the secondary risk to birds and the secondary risk to mammals since we believe that the overall importance of the persistence should equal that of the mortality observed in the toxicity studies (2.5 x 4 = 10). Finally, summary values for each of the four risk types (i.e., primary risk to birds, primary risk to mammals, secondary risk to birds, secondary risk to mammals) are calculated separately and then these summary values are analyzed together in a final overall analysis. An alternate approach is considered where all measure of effects are considered in one step. The results of different approaches are compared and discussed later in this appendix. Basically, the approach using separate risk calculations is chosen because it eliminated unequal weighting of one risk over another due to differences in the number of measures of effect.

The *DecideRight*® software is not used for the analysis; rather, *Lotus SmartSuite 1-2-3*® is used for all calculations .

Results of the Comparative Analysis Model

As noted above, the summary values for each of the four risk types are calculated separately and then these summary values are analyzed together in a final overall analysis. Decision tables and graphs of the sums of the weighted averages for each of the four risk types are presented separately below. At the end, the decision table and graph for the overall potential risk analysis is presented.

By way of example, a detailed explanation of how the comparative analysis model results presented in Table 2. - Greatest Primary Risk to Birds - are calculated, is provided here in a series of steps. The measure of effect values come from Table 1.

Step 1. Give a Weight (Importance Value) to each Measure of Effect

Both Measures of Effect for Primary Risk to Birds are given a weight of high =10.

Step 2. Normalize the Assigned Weights for each Measure of Effect

Divide each weight by the sum of the all weights, i.e. 10/20 = 0.5, and multiply the result by 10. Thus, the weight for each Measure of Effect = 5.

Step 3. Calculate the Weighted Average Values for Each Measure of Effect and each Bait

Substep A. The first measure of effect is the Mean Dietary Risk Quotient (ppm bait/LC50). The calculation for each rodenticide bait is: The RQ value for that rodenticide is divided by the Maximum RQ value for all the rodenticides; and, the result is multiplied by the normalized wight for the measure of effect. Specifically, for each rodenticide bait, the calculations are as follows:

Brodifacoum 50 ppm: (44.0/44.0)*5 = 5.00
Bromadiolone 50 ppm: (0.85/44.0)*5 = 0.10
Bromethalin 100 ppm: (0.35/44.0)*5 = 0.04
Chlorophacinone 100 ppm: (1.20/44.0)*5 = 0.14
Chlorophacinone 50 ppm: (0.60/44.0)*5 = 0.07
Cholecalciferol 750 ppm: (1.00/44.0)*5 = 0.11
Difethialone 25 ppm: (34.0/44.0)*5 = 3.86
Diphacinone 100 ppm: (0.10/44.0)*5 = 0.01
Diphacinone 50 ppm: (0.10/44.0)*5 = 0.01
Warfarin 250 ppm: (0.35/44.0)*5 = 0.04
Zinc Phosphide 20,000 ppm: (24.75/44.0)*5 = 2.81

Substep B. The second measure of effect is the No. Bait Pellets Needed for a 100 g Bird to Ingest LD50 Dose at a Single Feeding. The inverse of this measure of effect was used in order to correctly calculate the weighted averages and avoid skewed results. The Inverse of the No. Bait Pellets value for each rodenticide is divided by the Maximum

Inverse of the No. Bait Pellets value; then, this result is multiplied by the normalized weight for the measure of effect. Specifically, for each rodenticide bait, the calculations are as follows:

Brodifacoum 50 ppm: (0.3846/3.3333)*5 = 0.58
Bromadiolone 50 ppm: (0.0007/3.3333)*5 = 0.00
Bromethalin 100 ppm: (0.0435/3.3333)*5 = 0.07
Chlorophacinone 100 ppm: (0.0008/3.3333)*5 = 0.00
Chlorophacinone 50 ppm: (0.0004/3.3333)*5 = 0.00
Cholecalciferol 750 ppm: (0.0025/3.3333)*5 = 0.00
Difethialone 25 ppm: (0.1923/3.3333)*5 = 0.29
Diphacinone 100 ppm: (0.0005/3.3333)*5 = 0.00
Diphacinone 50 ppm: (0.0003/3.3333)*5 = 0.00
Warfarin 250 ppm: (0.0008/3.3333)*5 = 0.00
Zinc Phosphide 20,000 ppm: (3.3333/3.3333)*5 = 5.00

Step 4. Sum the Weighted Average Values for Both Measures of Effect for each Rodenticide Bait

The weighted average values calculated above are summed for each rodenticide bait to arrive at the sum of the weighted average values for primary risk to birds.

Brodifacoum 50 ppm: 5.00+0.58 = 5.58
Bromadiolone 50 ppm: 0.10+0.00 = 0.10
Bromethalin 100 ppm: 0.04+0.07 = 0.10
Chlorophacinone 100 ppm: 0.14+0.00 = 0.14
Chlorophacinone 50 ppm: 0.07+0.00 = 0.07
Cholecalciferol 750 ppm: 0.11+0.00 = 0.12
Difethialone 25 ppm: 3.86+0.29 = 4.15
Diphacinone 100 ppm: 0.01+0.00 = 0.10
Diphacinone 50 ppm: 0.01+0.00 = 0.01
Warfarin 250 ppm: 0.04+0.00 = 0.04
Zinc Phosphide 20,000 ppm: 2.81+5.00 = 7.81

The summary values above, in ranked order from highest to lowest, are found in Table 2, and Figure 1 presents a graph of the calculations. Rounding affects some of the calculations.

Results of Comparative Analysis for Primary Risk to Birds

The question *"Which of the 11 Rodenticide Baits Pose the Greatest Primary Risk to Birds?"* is analyzed by the comparative model and the results are presented in a table (Table 2). The sum of the weighted average values for primary risk to birds is found in the ‘Summary Values” column in Table 2, and graphically shown in Figure 1. The results are based on two measures of effect: Mean Dietary Risk Quotient (ppm bait/LC50) and the Inverse of the No. Bait Pellets Needed for 100-g Bird to Ingest LD50 at Single Feeding. Of all the rodenticide baits considered, three are considered to pose the greatest potential primary risk to birds:

Zinc Phosphide 20,000 ppm
Brodifacoum 50 ppm
Difethialone 25 ppm

Based on this analysis, zinc phosphide poses the greatest potential primary risk to birds. The Inverse of the No. Bait Pellets Needed for 100-g Bird to Ingest LD50 at Single Feeding appears to be the most significant measure of effect leading to the conclusion that zinc phosphide poses greater risk to birds than brodifacoum. It also appears to be the most significant measure of effects leading to the conclusion that zinc phosphide poses greater potential primary risk to birds than difethialone. Brodifacoum has a higher summary risk value for one of the two measures of effect, mean dietary risk quotient (ppm ai bait/LC50), than both zinc phosphide and difethialone. Difethialone also has a higher summary risk value for one of the two measures of effect, mean dietary risk quotient (ppm ai bait/LC50), than zinc phosphide.

Table 2. Decision Table: Greatest Primary Risk to Birds.

	Mean Dietary Risk Quotient (ppm bait/ LC50)	*Inverse of No. Bait Pellets Needed for 100gm Bird to Ingest LD50 Dose at Single Feeding*	*Summary Values*
Alternative Pesticides	Measure of Effect Values		
Brodifacoum 50ppm	44.00	0.38	5.58
Bromadiolone 50ppm	0.85	0.00	0.10
Bromethalin 100ppm	0.35	0.04	0.10
Chlorophacinone 100ppm	1.20	0.00	0.14
Chlorophacinone 50ppm	0.60	0.00	0.07

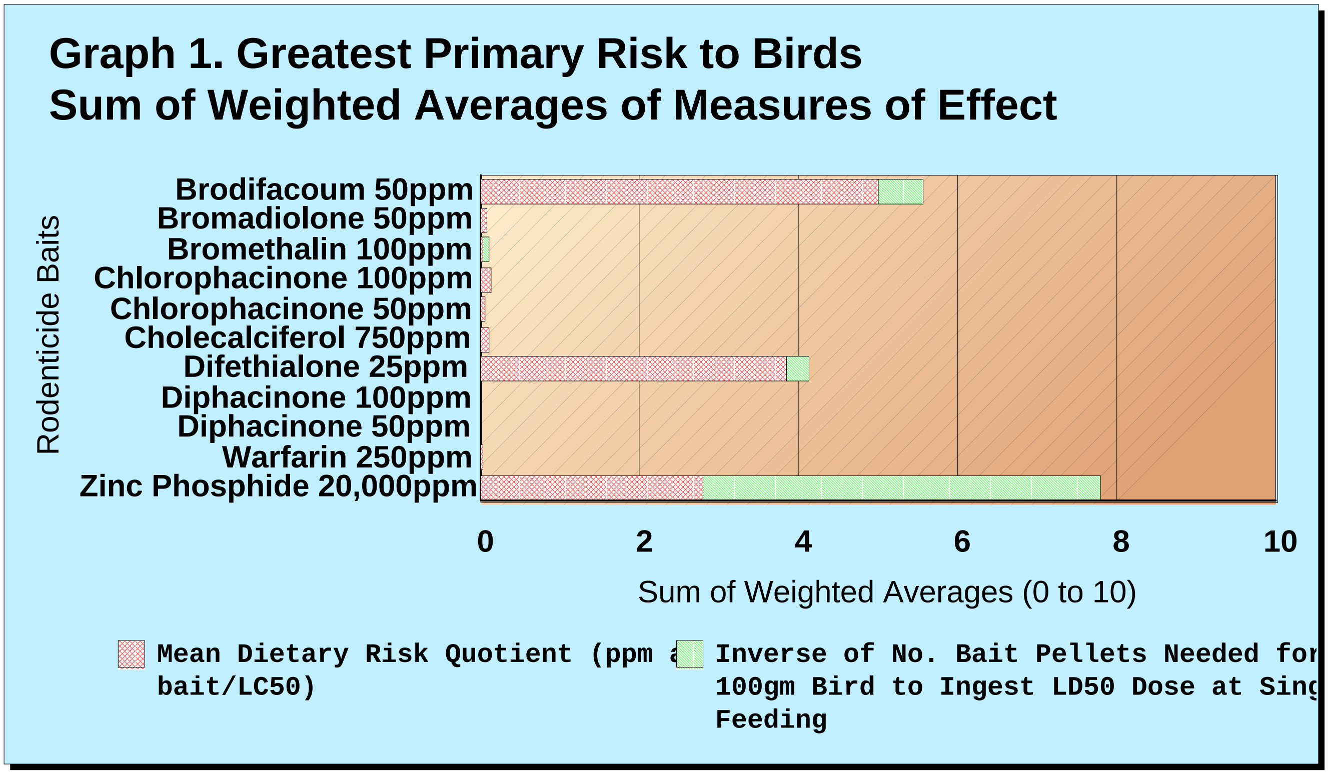
Diphacinone 50ppm	0.10	0.00	0.01
Warfarin 250ppm	0.35	0.00	0.04
Zinc Phosphide 20,000ppm	24.75	3.33	7.81



Graph 1. Greatest Primary Risk to Birds
Sum of Weighted Averages of Measures of Effect

Results of Comparative Analysis for Primary Risk to Mammals

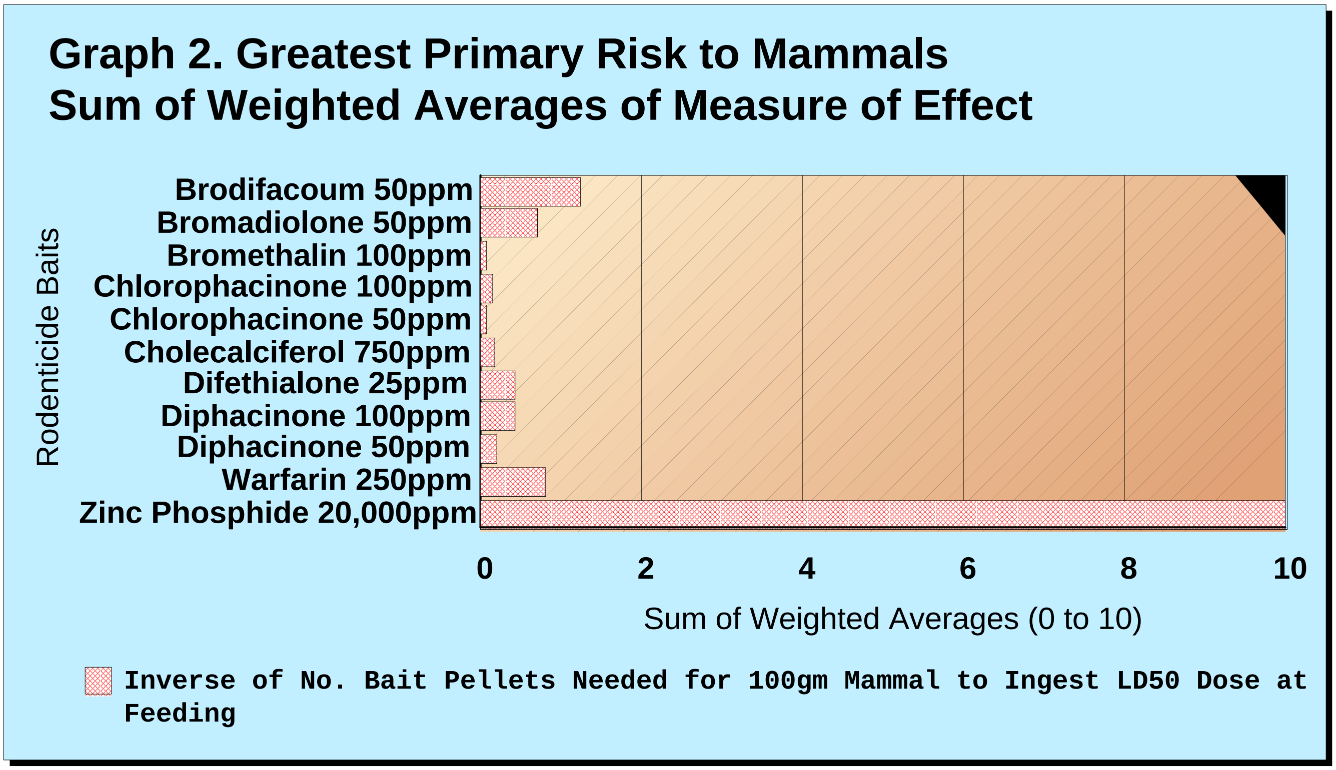
The question *"Which of the 11 Rodenticide Baits Pose the Greatest Primary Risk to Mammals?*" is analyzed by the comparative model and the results are presented in a table (Table 3). The sum of the weighted average values for primary risk is found in the 'Summary Values" column in Table 3, and graphically shown in Figure 2. The results are based on a single measure of effect: Inverse of the No. Bait Pellets Needed for 100-g Mammal to Ingest an LD50 Dose at a Single Feeding. Of all the rodenticide baits considered, one is considered to pose the greatest potential primary risk be mammals:

Zinc Phosphide 20,000 ppm

Based on this analysis, zinc phosphide poses the greatest potential primary risk to mammals by a substantial margin over the other rodenticide baits. Warfarin and brodifacoum are in distant second and third place.

Table 3. Greatest Primary Risk to Mammals.

	Inverse of No. Ba Pellets Needed for 100gm Mammal to Ingest LD50 Dose at Single Feeding	*Summary Values*
Alternative Pesticides	Measure of Effect Value	
Brodifacoum 50ppm	0.25	1.25
Bromadiolone 50ppm	0.14	0.71
Bromethalin 100ppm	0.02	0.10
Chlorophacinone 100ppm	0.03	0.16
Chlorophacinone 50ppm	0.02	0.08
Cholecalciferol 750ppm	0.04	0.18
Difethialone 25ppm	0.09	0.45
Diphacinone 100ppm	0.09	0.43
Diphacinone 50ppm	0.04	0.22
Warfarin 250ppm	0.17	0.83
Zinc Phosphide 20,000ppm	2.00	10.00



Graph 2. Greatest Primary Risk to Mammals
Sum of Weighted Averages of Measure of Effect

Results of Comparative Analysis for Secondary Risk to Birds

The question *"Which of the 11 Rodenticide Baits Pose the Greatest Secondary Risk to Birds ?"* is analyzed by the comparative model and the results are presented in a table (Table 4). The sum of the weighted average values for secondary risk to birds is found in the 'Summary Values" column in Table 4, and graphically shown in Figure 3. The results are based on three measures of effect: Mean % Mortality of Secondary Lab Studies, Blood Retention Time (Days), Liver Retention Time (Days). Of all the rodenticide baits considered, two are considered to pose the greatest potential secondary risk to birds:

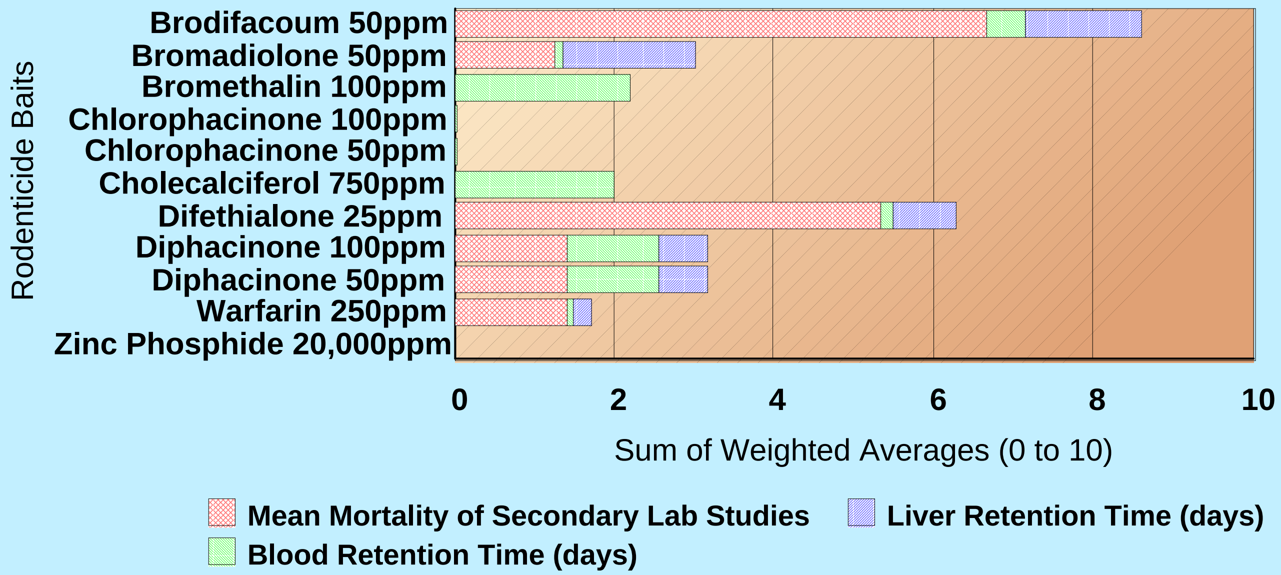
Brodifacoum 50 ppm
Difethialone 25 ppm

Based on this analysis, brodifacoum poses the greatest potential secondary risk to birds, and by a substantial margin over difethialone. Brodifacoum had higher summary values for all three measures of effect. Mean (%) Mortality of Secondary Lab Studies appears to be the most significant measure of effect leading to the conclusion that brodifacoum poses greater risk than difethialone.

Table 4. Greatest Secondary Risk to Birds.

	Mean Mortality of Secondary Lab Studies	Blood Retention Time (days)	Liver Retention Time (days)	*Summary Values*
Alternative Pesticides	Measures of Effect Value			
Brodifacoum 50ppm	42.00	7.30	217.00	8.60
Bromadiolone 50ppm	8.00	1.40	248.00	3.03
Bromethalin 100ppm	No Data	5.60	No Data	2.20
Chlorophacinone 100ppm	0.00	0.40	No Data	0.03
Chlorophacinone 50ppm	0.00	0.40	No Data	0.03
Cholecalciferol 750ppm	0.00	25.50	No Data	2.00
Difethialone 25ppm	33.60	2.50	117.70	6.29
Diphacinone 100ppm	9.00	17.50	90.00	3.18
Diphacinone 50ppm	9.00	17.50	90.00	3.18
Warfarin 250ppm	9.00	0.82	35.00	1.72
Zinc Phosphide 20,000ppm	0.00	No Data	No Data	0.00

Results of Comparative Analysis for Secondary Risk to Mammals



Graph 3. Greatest Secondary Risk to Birds
Sum of Weighted Averages of Measures of Effect

The question *"Which of the 11 Rodenticide Baits Pose the Greatest Secondary Risk to Mammals?"* is analyzed in the comparative analysis model and the results are presented in a table (Table 5). The sum of the weighted average values for secondary risk to mammals is found in the 'Summary Values" column in Table 5, and graphically shown in Figure 4. The results are based on three measures of effect: Mean % Mortality of Secondary Lab Studies, Blood Retention Time (Days), Liver Retention Time (Days). Of all the rodenticide baits considered, five are considered to pose the greatest potential secondary risk to mammals:

Diphacinone 100 ppm
Diphacinone 50 ppm
Chlorophacinone 100 ppm
Chlorophacinone 50 ppm
Brodifacoum 50 ppm

Based on this analysis, diphacinone (100 ppm and 50 ppm baits) pose the greatest potential secondary risk to mammals. Both rodenticide baits had identical summary risk values. Blood Retention Time (days) appears to be the most significant measure of effect leading to the conclusion that both of these diphacinone baits pose greater secondary risk to mammals than the chlorophacinone baits (100 ppm and 50 ppm baits). Both of the chlorophacinone baits had identical summary risk values as well. Mean (%) Mortality of Secondary Lab Studies appears to be the most significant measure of effect leading to the conclusion that both baits of diphacinone and chlorophacinone pose greater secondary risk to mammals than brodifacoum.

Table 5. Greatest Secondary Risk to Mammals.

	Mean Mortality of Secondary Lab Studies	Blood Retention Time (days)	Liver Retention Time (days)	*Summary Values*
Alternative Pesticides	Measures of Effect Value			
Brodifacoum 50ppm	42.00	7.30	217.00	6.76
Bromadiolone 50ppm	23.00	1.40	248.00	4.40
Bromethalin 100ppm	0.00	5.60	No Data	0.44

Results of Comparative Analysis for Overall Risk to Birds and Mammals

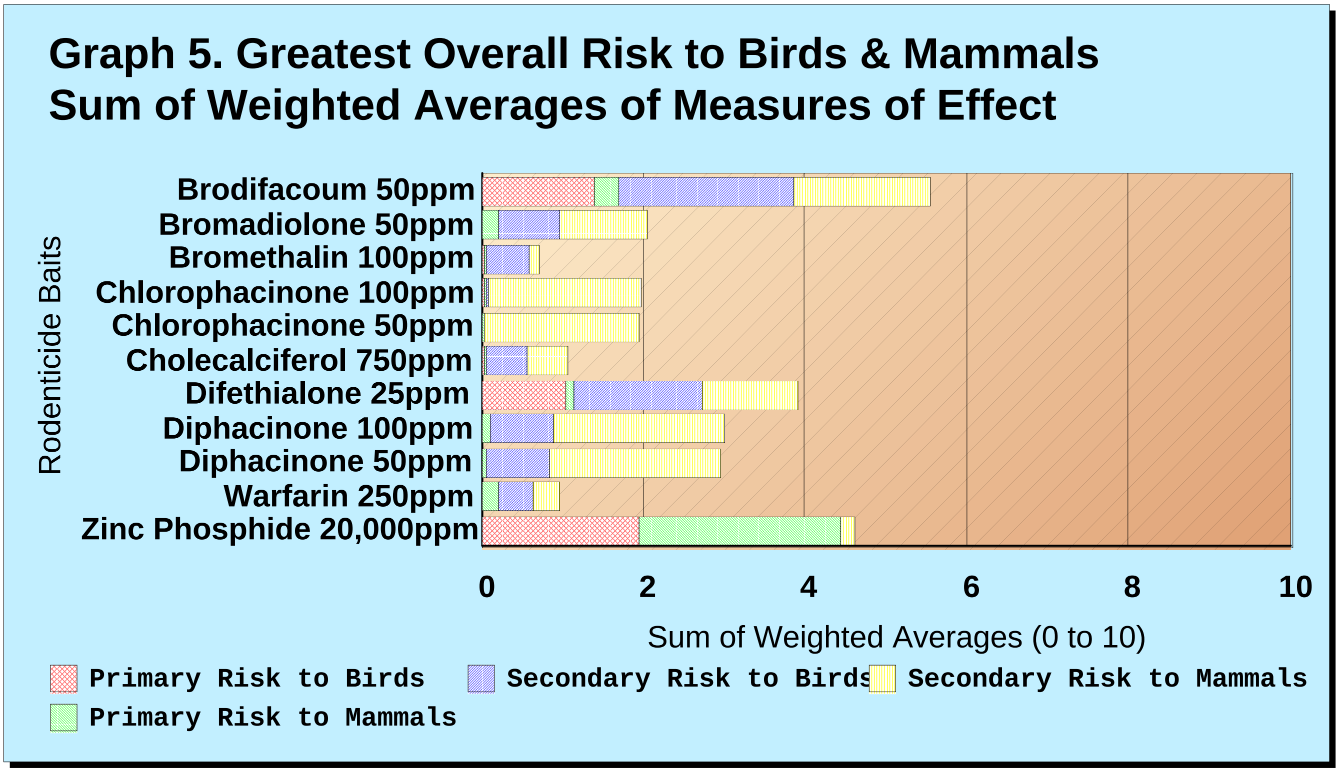
The question *"Which of the 11 Rodenticide Baits Pose the Greatest Overall Risk to Birds and Mammals?"* is analyzed by the comparative analysis model and the results are presented in a table (Table 6). The sum of the weighted average values for overall risk to birds and mammals is found in the 'Summary Values" column in Table 6, and graphically shown in Figure 5. The results are based on four types of risk, which in this case are the four measures of effect: Primary Risk to Birds, Primary Risk to Mammals, Secondary Risk to Birds, and Secondary Risk to Mammals. Of all the rodenticide baits considered, three are considered to pose the greatest potential overall risk to birds and mammals:

Brodifacoum 50 ppm
Zinc Phosphide 20,000 ppm
Difethialone 25 ppm

Based on this analysis, brodifacoum poses the greatest overall potential risk to birds and mammals and by a substantial margin over the other rodenticide baits. Brodifacoum has higher summary risk values than zinc phosphide for two of the four measures of effect. Secondary Risk to Birds and Secondary Risk to Mammals appear to be the most significant measures of effect leading to the conclusion that brodifacoum poses greater overall potential risk to birds and mammals than zinc phosphide. Zinc phosphide has higher summary risk values than difethialone for two of the four measures of effect, and Primary Risk to Mammals and Primary Risk to Birds appear to be the most significant measures of effect leading to the conclusion that zinc phosphide poses greater overall risk to birds and mammals than difethialone. Difethialone has higher summary risk values than both diphacinone baits (100 ppm and 50 ppm) for three of the four measures of effect, and Primary Risk to Birds appears to be the most significant measure of effect leading to the conclusion that difethialone poses greater overall potential risk to birds and mammals than both diphacinone baits.

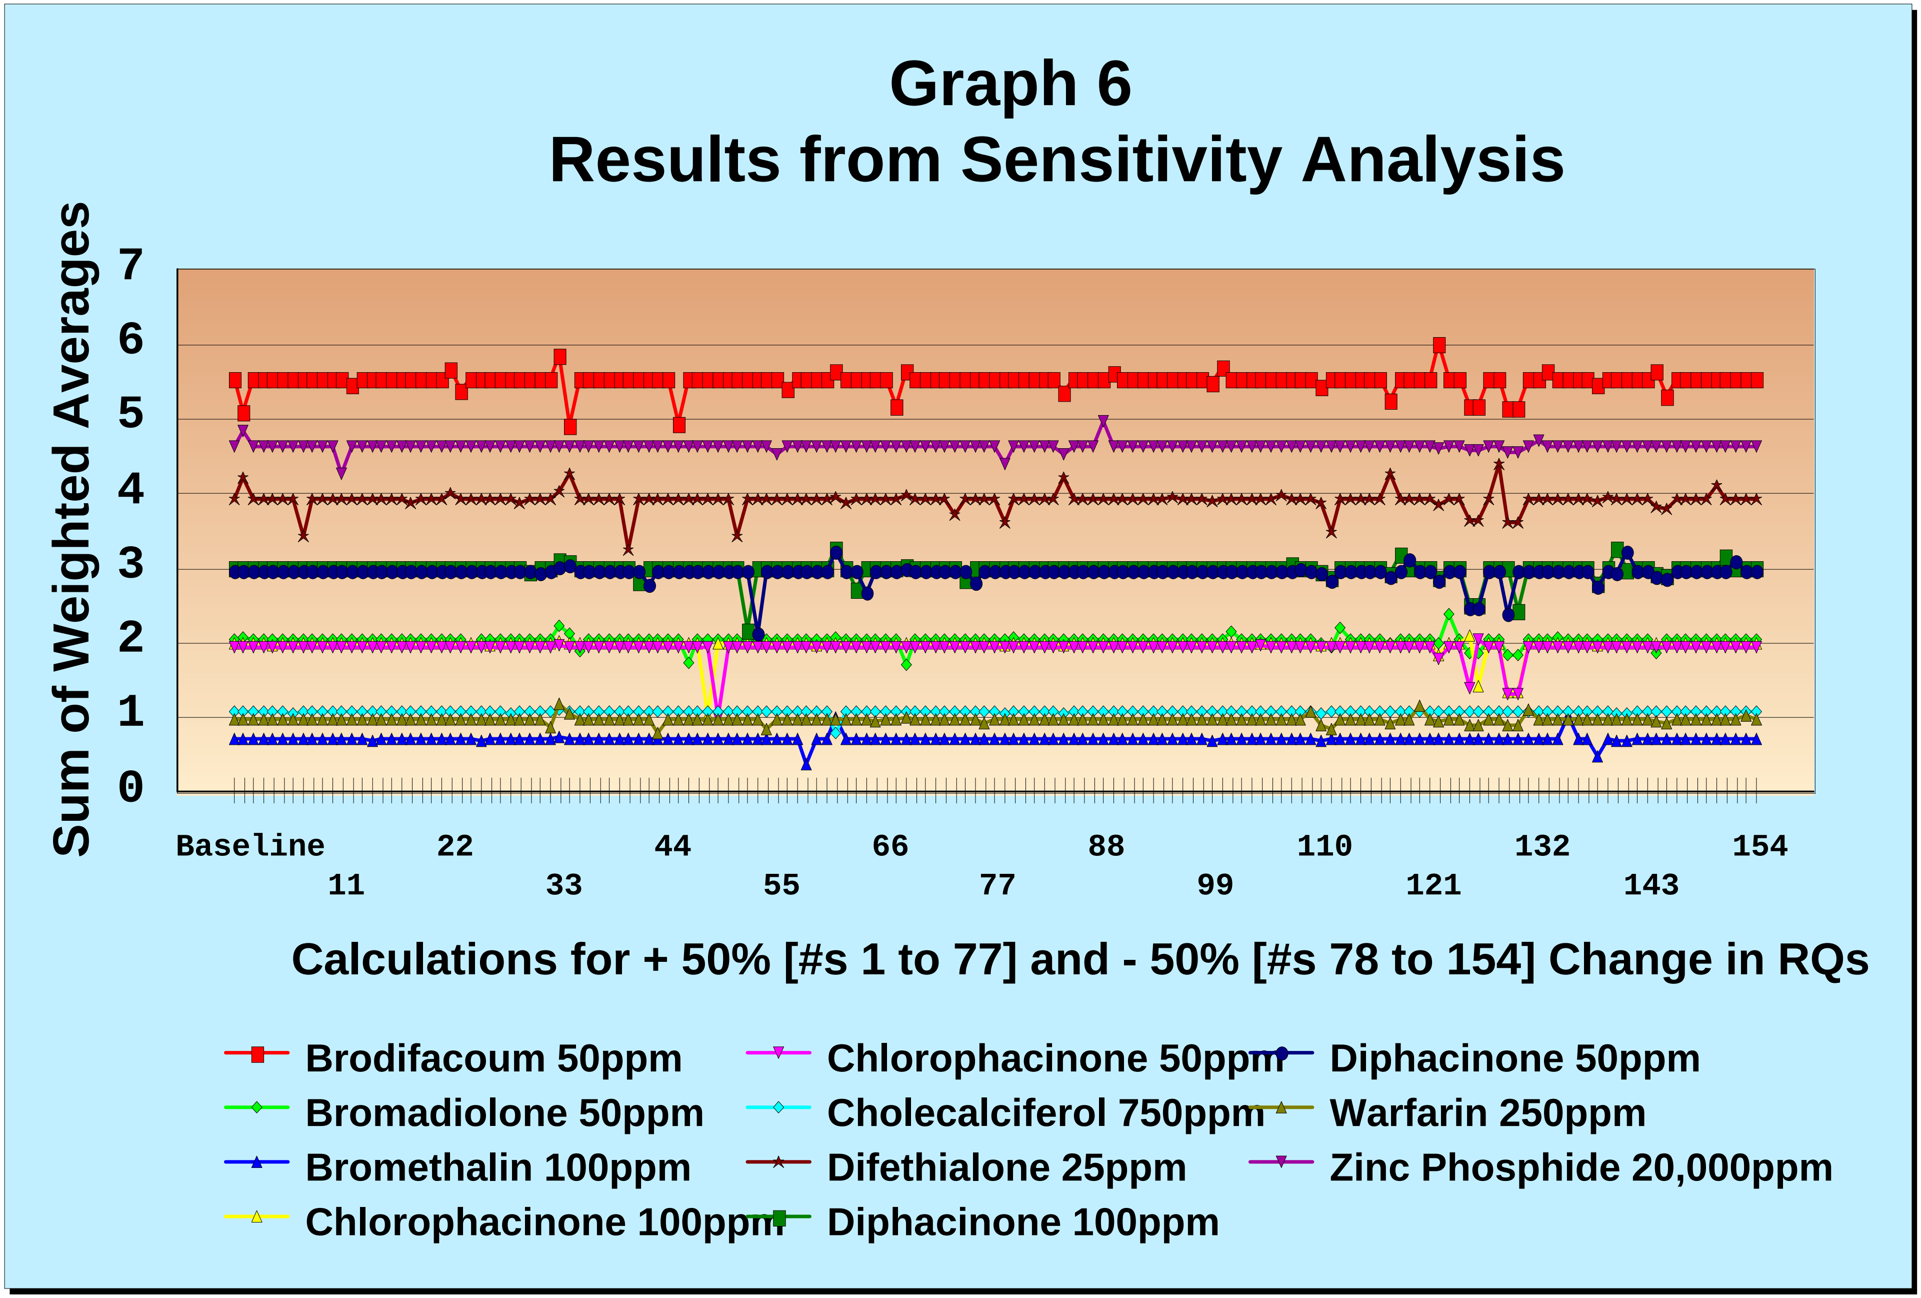
Table 6. Greatest Overall Risk to Birds and Mammals.

	Primary Risk to Birds	Primary Risk to Mammals	Secondary Risk to Birds	Secondary Risk to Mammals	***Summary Values***
Alternative Pesticides	Measures of Effect Value				
Brodifacoum 50ppm	5.58	1.25	8.60	6.76	5.55
Bromadiolone 50ppm	0.10	0.71	3.03	4.40	2.06
Bromethalin 100ppm	0.10	0.10	2.20	0.44	0.71
Chlorophacinone 100ppm	0.14	0.16	0.03	7.62	1.99
Chlorophacinone 50ppm	0.07	0.08	0.03	7.62	1.95
Cholecalciferol 750ppm	0.12	0.18	2.00	2.00	1.07
Difethialone 25ppm	4.15	0.45	6.29	4.82	3.93
Diphacinone 100ppm	0.01	0.43	3.18	8.42	3.01
Diphacinone 50ppm	0.01	0.22	3.18	8.42	2.96
Warfarin 250ppm	0.04	0.83	1.72	1.32	0.98
Zinc Phosphide 20,000ppm	7.81	10.00	0.00	0.69	4.63



Results of Sensitivity Analysis

As previously noted, the FIFRA SAP recommended performing a sensitivity analysis. Specifically, they suggested that *“it would be useful to test the rankings by changing the values of the input variables...to lend insight to the robustness of the rankings, increase the confidence in the predictions, and move toward a better understanding of the effect that varying levels of uncertainty can have on the predictions.”* This is also a recommendation from a number of the peer reviewers. Therefore, to study how changes in each measure of effect value could affect the overall summary risk results presented above (Table 6 and Graph 5), a simple sensitivity analysis is performed using two scenarios: (1) vary each individual risk rating +50%, and -50%; and , (2) select certain risk rating that appeared to show a sensitivity to change, extend the change up to 90% (+ or -) or more. Thus, for the first scenario, each measure of effect value is separately decreased by 50%, and then increased by 50%. The percentage 50% is chosen arbitrarily, with the intention of choosing greater percentages for change in the second scenario after viewing these results. The changes in the overall summary risk values found in Table 6 as a result of the change in each measure of effect value, are recorded. The overall summary risk values in Table 6 are the baseline values. The results of the 154 changes in the summary risk values are presented in Graph 6.



Graph 6
Results from Sensitivity Analysis

With a 50 % (+ or -) change in the measure of effect values, the ranked positions for brodifacoum, zinc phosphide, and difethialone do not change, indicating that the ranking is robust at this level of change. However, the ranked positions of the other rodenticide baits change numerous times, as indicated by the numerous times the lines cross each other. A few of the changes do result in lower values for brodifacoum, such as #s 1, 34, 45 and 67, or higher values for zinc phosphide, such as #s 1 and 88, or higher values for difethialone, such as # 128. To further test the rankings, the measures of effect values for these numbers are increased to 90% (+ or -) or greater and the resultant overall summary risk values are presented below:

> #1, Reduction in the Mean Dietary Risk Quotient (ppm bait/LC50), one measure of effect for primary risk to birds for brodifacoum, of 50%, 67%, 70% and 90% resulted in the following ranking of overall summary risk values:

	Brodifacoum 50ppm	Brodifacoum 50ppm	Brodifacoum 50ppm	Brodifacoum 50ppm
Alternative Pesticides	**Summary Values**	**Summary Values**	**Summary Values**	**Summary Values**
Brodifacoum 50ppm	5.11	4.83	**4.78**	**4.46**
Bromadiolone 50ppm	2.07	2.07	2.07	2.07

Diphacinone 100ppm	3.01	3.01	3.01
Diphacinone 50ppm	2.96	2.96	2.96
Warfarin 250ppm	0.98	0.98	0.98
Zinc Phosphide 20,000ppm	4.63	4.63	4.63
	50%	76%	90%

<u>Results</u>: A reduction in the Mean (%) Mortality of Secondary Lab Studies on Mammals, one of two measures of effect for secondary risk to mammals for brodifacoum, of greater

than 76% would result in zinc phosphide moving ahead of brodifacoum as the rodenticide bait posing the greatest overall potential risk to birds and mammals.

#128, Increase in the Mean (%) Mortality of secondary Lab Studies on Mammals, one measure of effect for secondary risk to mammals for difethialone, of 50% and 99%, resulted in the following ranking of overall summary risk values:

	Difethialone 25ppm	Difethialone 25ppm
Alternative Pesticides	**Summary Values**	**Summary Values**
Brodifacoum 50ppm	5.55	5.39
Bromadiolone 50ppm	2.06	1.97
Bromethalin 100ppm	0.71	0.71
Chlorophacinone 100ppm	1.99	1.74
Chlorophacinone 50ppm	1.95	1.70
Cholecalciferol 750ppm	1.07	1.07
Difethialone 25ppm	4.41	**4.63**
Diphacinone 100ppm	3.01	2.79
Diphacinone 50ppm	2.96	2.73
Warfarin 250ppm	0.98	0.94
Zinc Phosphide 20,000ppm	4.63	**4.60**
	50%	**99%**

<u>Results</u>: An increase in the Mean (%) Mortality of Secondary Lab Studies on Rodents, one of two measures of effect for secondary risk to mammals for difethialone, of 99% would result in difethialone moving ahead of zinc phosphide as the rodenticide bait posing the second greatest overall potential risk to birds and mammals.

None of the following changes resulted in changes in rankings of brodifacoum, zinc phosphide or difethialone: a 99% reduction in Liver Retention Time (days) for brodifacoum (#67); a 99% increase in the Mean Avian Dietary Risk Quotient for zinc phosphide (#88); a 99% increase in the Mean (%) Mortality of secondary Lab Studies on Mammals for difethialone.

The sensitivity analysis shows that the ranking for the rodenticide baits which pose the greatest potential risk to birds and mammals is robust when the measures of effect are changed by +/- 50%. The ranking is generally robust when the measures of effect are changed by +/- 99%. However, a reduction of greater than 67% in the Mean Dietary Risk Quotient for brodifacoum, 64% in the Mean (%) Mortality of Secondary Lab Studies on Birds for brodifacoum, and 76% in the Mean (%) Mortality of Secondary Lab Studies on Mammals f or brodifacoum, would result in zinc phosphide moving ahead of brodifacoum as posing the greatest overall risk to birds and mammals. In addition, an increase of 99% in the Mean (%) Mortality of Secondary Lab Studies on Mammals for difethialone would result in difethialone moving ahead of zinc phosphide as posing the second greatest overall risk to birds and mammals. Thus, the sensitivity analysis shows that the ranking for the rodenticide baits is generally robust. With few exceptions we can confidently say that brodifacoum poses the greatest overall potential risk to birds and mammals, followed by zinc phosphide and difethialone.

Results Using Toxicity Reference Values for Birds

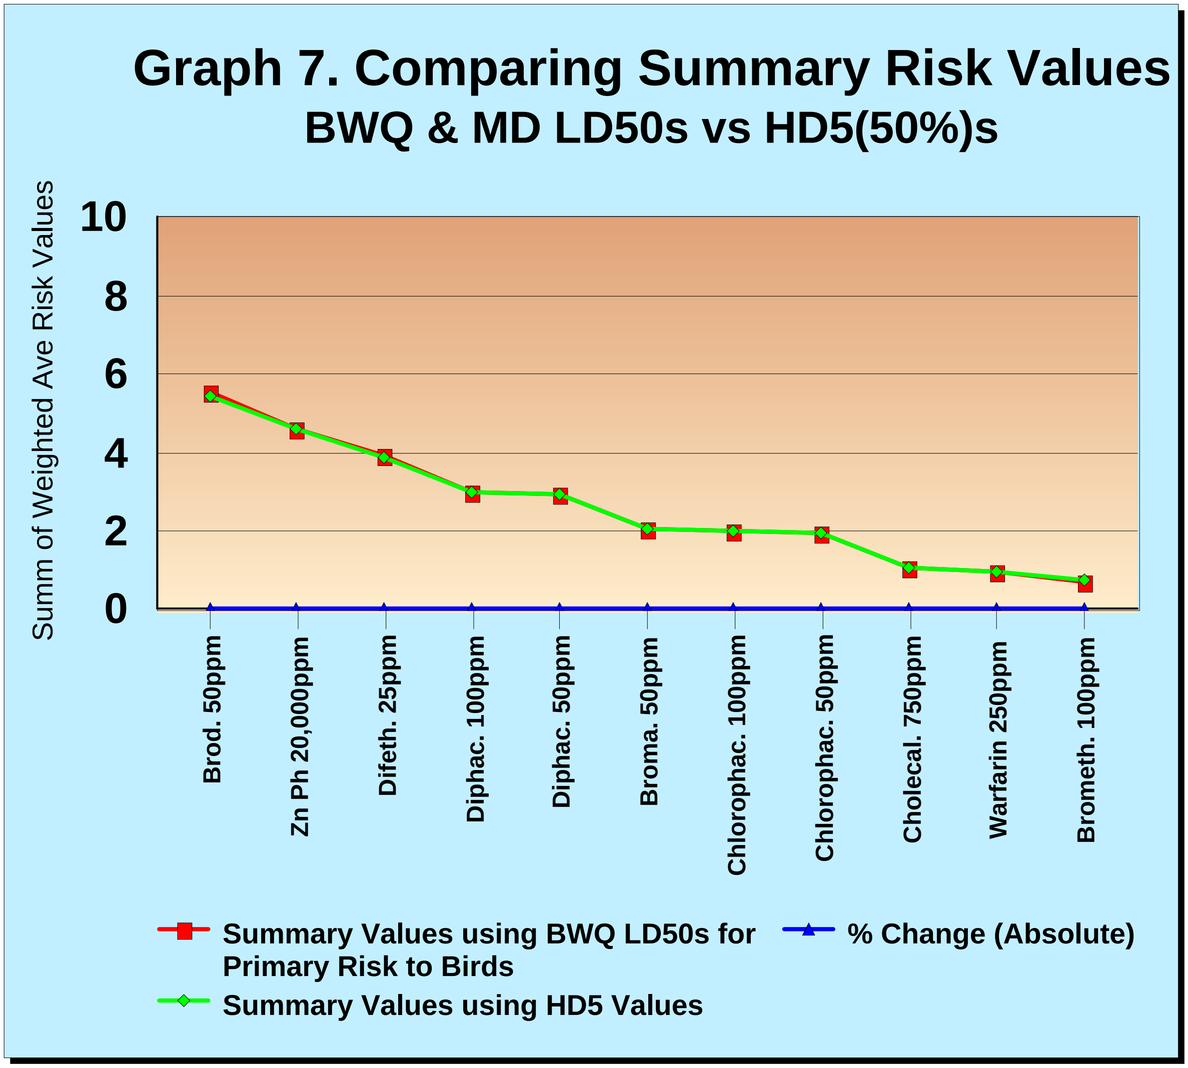
Mineau *et al* (2001) state that *"when carrying out comparative assessments for pesticides, it is essential to use the most unbiased data possible."* They suggest a distribution approach for avian LD50 data, modified (1) to incorporate body-weight scaling, and (2) to use extrapolation factors for pesticides for which there are insufficient data from which to derive a distribution. *"A distribution-based approach uses the pesticide-specific data available to define the shape of the distribution through the estimation of a mean and variance for the distribution."* As the authors note, *"Working with a distribution allows one to set a desired percentile, or threshold LD50 value sufficiently protective for an arbitrarily chosen portion of the entire population of bird species."* They follow other authors and arbitrarily set the protection level at the 5th percentile of the species distribution, which they term the Hazardous Dose 5% or HD_5. Further, they fixed the level of certainty at 50%. Thus, the HD_5(50%) reference value is the 5% tail of the avian LD50 toxicity distribution calculated with 50% probability of overestimation. They believe that this *"approach of using reference values based on species specific extrapolation factors represents the most unbiased attempt to date to compare the toxicity of pesticides for which many data points are available with those about which we know very little."*

Since HD_5(50%) reference values are available for all rodenticides but diphacinone (Table 3 in Mineau *et al*), these values are substituted for the LD50 values for bobwhite quail or mallard duck used in the measure of effect - Inverse the No. Bait Pellets Needed for a 100-g Bird LD50 Dose at a Single Feeding in the comparative analysis for Primary Risk to Birds.

Rodenticide	HD_5(50%)
Brodifacoum 50 ppm	0.81
Bromadiolone 50 ppm	53.26
Bromethalin 100 ppm	0.83
Chlorophacinone 100 ppm	3.32
Chlorophacinone 50 ppm	4.98
Cholecalciferol 750 ppm	192.68
Difethialone 25 ppm	0.31
Diphacinone 100 ppm	No Data
Diphacinone 50 ppm	No Data
Warfarin 250 ppm	120.21
Zinc Phosphide 20,000 ppm	5.45

Since bait-specific HD_5(50%)s are not available, the HD_5(50%) value from Mineau *et al* is applied to the highest active ingredient concentration of two baits, and it is reduced by the proportion difference in active ingredient concentrations between baits and applied to the bait with the lower active ingredient concentration. Lacking slope data, this assumes a linear relationship between the active ingredient in the bait and the acute toxicity to birds. Finally, the overall summary values for risk to birds and mammals are calculated and compared to the baseline in Table 6 and Graph 5. The results of the analysis are presented in Graph 7.

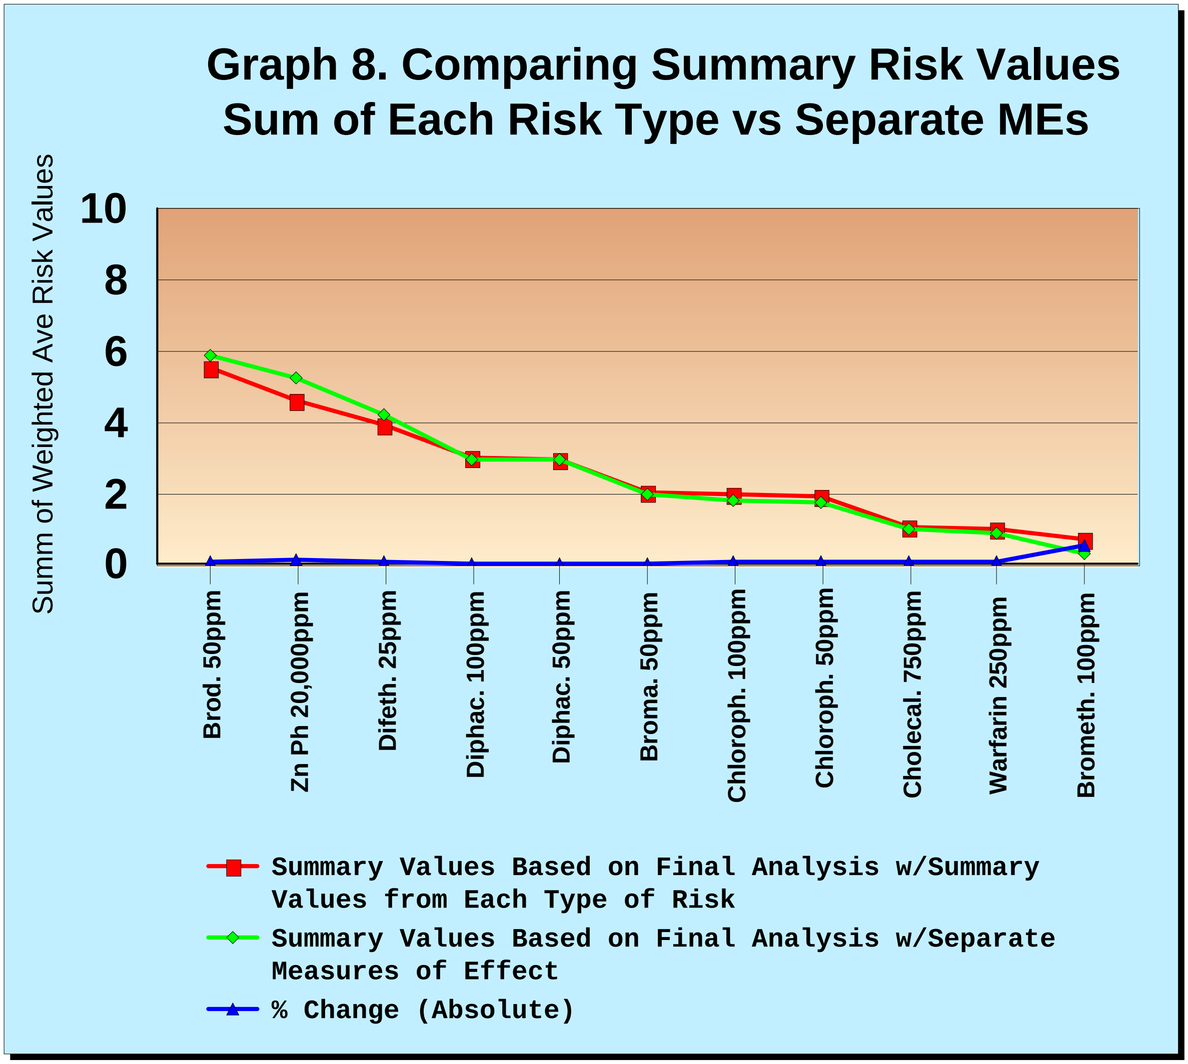
This analysis shows that the ranking remains the same and the use of the HD_5(50%) values from Mineau *et al* in place of the LD50 values for bobwhite quail or mallard duck does not have any affect on ranking of the rodenticide baits posing the greatest overall potential risk to birds and mammals. Missing HD_5(50%)data for diphacinone adds uncertainty to this conclusion.



Graph 7. Comparing Summary Risk Values
BWQ & MD LD50s vs HD5(50%)s

As noted previously, the approach taken for this analysis is to separately analyze the risk for each risk type, then analyze the summary values for each of the four risk types together in a final overall analysis. Each type of risk included variable and unequal numbers of measures of effect. Analyzing them separately and then using their summary values to arrive at an overall risk value eliminated unequal weighting of one type of risk over another due to differences in the number of measures of effect.

An alternate approach is considered where the unequal weighting is ignored and all measure of effects are considered in one step. The weights are all rated high (10.0), except for blood retention and liver retention, which are weighted medium (5.0) so that the total contribution of persistence is rated equal to the other measures of effect (10.0). The overall summary risk values are calculated and compared to the baseline results in Table 5 and Graph 6. The results of this analysis is presented in Graph 8. The rankings for overall risk to birds and mammals do not change. Thus in this case, the unequal weighting of one type of risk over another due to differences in the number of measures of effect does not appear to have a significant effect on the overall ranking.



Graph 8. Comparing Summary Risk Values
Sum of Each Risk Type vs Separate MEs

Incidents

Bird and mammal incidents provide additional information to further characterize the risk of rodenticide baits. The collection and reporting of incidents is not systematic, and the presence or absence of incidents is also affected by the extent of use of the rodenticide bait as well as other factors. Thus, the existence of incidents for a rodenticide bait can be viewed as confirming the risk, where as the absence of them says little about the risk. Further, without more information than is typically available for most incident reports, it can sometimes be difficult to separate the incidents based on primary or secondary effects.

Based on Table 42 in the main document, there are a large number of bird and mammal incidents reported for rodenticide baits (161 birds; 119 mammal; 280 total). Reported mortality is attributed to both primary and secondary effects. The incidents reported for each rodenticide bait (where two baits are included in the analysis, the one with the highest concentration in the bait formulation is used) are plotted on the x-axis against the summary values of the weighted averages for the overall risk to birds and mammals (See summary values, Table 6) on the y-axis. The incidents are ‘turned around’ so that the rodenticide baits with the greatest number of reported incidents and the largest summary risk values should appear in the upper left of the graph. Tables 7, 8 and 9 show the input values for the following graphs. Graph 9 presents the bird incidents; Graph 10, the mammal incidents; and Graph 11, both combined.

The graphs confirm that brodifacoum is the rodenticide bait that poses the greatest overall potential risk to birds and mammals. In addition to brodifacoum, Graph 9 also identifies bromadiolone and zinc phosphide as potential concerns for birds, while Graph 10 identifies bromadiolone, diphacinone, and chlorophacinone as potential risk concerns for mammals.

Conclusions

Based on the comparative analysis model called the simple multi-attribute rating technique or SMART, the potential risks of 11 rodenticide baits are compared based on a number of measures of effect values for primary and secondary risk to birds and mammals. Of all the rodenticide baits considered, three are considered to pose the greatest overall potential risk to birds and mammals: brodifacoum, zinc phosphide, and difethialone. Brodifacoum poses the greatest overall potential risk to birds and mammals, and by a substantial margin over the other rodenticide baits. Brodifacoum has higher summary risk values than zinc phosphide for both secondary risk to birds and secondary risk to mammals. Zinc phosphide has higher summary risk values than difethialone for both primary risk to birds and primary risk to mammals.

A sensitivity analysis is performed to identify the most sensitive measure of effect(s) and to determine if changes of 50% or more in these sensitive measures of effect would change the results of the analysis. This analysis shows that the ranking for the rodenticide baits which pose the greatest risk to birds and mammals is robust when the measures of effect are changed by +/- 50%. The ranking is generally robust when the measures of effect are changed by +/- 99%, with the following exceptions: a reduction of greater than 67% in the Mean Dietary Risk Quotient for brodifacoum, 64% in the Mean (%) Mortality of Secondary Lab Studies on Birds for brodifacoum, and 76% in the Mean (%) Mortality of Secondary Lab Studies on Mammals for brodifacoum, would result in zinc phosphide moving ahead of brodifacoum as posing the greatest overall risk to birds and mammals; and, an increase of 99% in the Mean (%) Mortality of Secondary Lab Studies on Mammals for difethialone would result in difethialone moving ahead of zinc phosphide as posing the second greatest overall potential risk to birds and mammals. Thus, the sensitivity analysis shows that the ranking for the rodenticide baits is generally robust. With few exceptions, we can say that brodifacoum poses the greatest overall potential risk to birds and mammals, followed by zinc phosphide and difethialone.

Acute toxicity reference values for rodenticides to birds and an alternative approach are also considered. The toxicity reference values from a recent publication are substituted for the avian LD50 values for bobwhite quail and mallard ducks that were used in one of the avian measures of effect. The results show that the overall ranking remains the same and the use of these toxicity reference values do not affect the analysis. When unequal weighting of measures of effect for each type of risk is ignored and all measures of effect are considered together, again the results show that the overall ranking does not change. Unequal weighting of type of risk over another, in this case, does not appear to have a significant effect on the overall ranking.

There are two factors which could contribute the greatest uncertainty to the analysis: (1) missing data, especially field mortality data for difethialone, and blood and liver retention values for a number of rodenticides; and (2) the assumption that field mortality to birds and mammals due to difethialone would likely equal 80% of that reported for brodifacoum. This assumption is based on the many chemical similarities between these two rodenticides, because difethialone is formulated at a lower % ai than brodifacoum, and the fact that less difethialone is used compared to brodifacoum.

The available incidents for birds and mammals are analyzed and compared the summary of the weighted average risk values. The results confirm that brodifacoum is the rodenticide bait that poses the greatest overall potential risk to birds and mammals, but they also identify bromadiolone and zinc phosphide as potential concerns for birds, and bromadiolone, diphacinone (100 ppm), and chlorophacinone (100 ppm) as potential concerns for mammals.

Attachment D: Incident Data For Birds and Nontarget Mammals

The incidents reported here are summarized for each rodenticide from incident reports in the EPA/OPP Environmental Fate and Effect Division's Ecological Incidents Information System. Unless otherwise noted, an incident is included here only if confirmation of exposure is reported. For the anticoagulants, detection of residue in the liver is the criterion of exposure unless otherwise stated. Hemorrhaging and other signs of toxicosis also generally are included in incident reports, but details are not tabulated here (see Stone et al. 1999, 2003; Hosea 2000). For the non-anticoagulants, detection of bait in the stomach or crop contents are typical evidence of exposure. Most of the incidents are based on carcass recovery; however, as noted, 3 incidents involved mammals that were live-trapped and sacrificed. Reported residue levels are provided only as confirmation that animals were exposed to a rodenticide. There are no incident data for bromethalin and cholecalciferol.

[a] reported in Johnson and Fagerstone (1992) and Hegdal and Gatz (1977)

Attachment E. USFWS Jeopardy Determinations for Effects of 8 Rodenticides on Threatened and Endangered Species.

In response to a formal consultation requested by EPA (1991b) under Section 7 of the Endangered Species Act, the United States Fish and Wildlife Service issued a Biological Opinion on *Effects of 16 Vertebrate Control Agents On Threatened and Endangered Species* in March of 1993 (USFWS 1993). The Biological Opinion included jeopardy determinations for species potentially exposed (primary or secondary exposure) to brodifacoum, bromadiolone, chlorophacinone, diphacinone, warfarin, bromethalin, zinc phosphide, and cholecalciferol. For each species addressed in the Biological Opinion, the Service determined either that use of the rodenticide "is likely to jeopardize" or "is not likely to jeopardize" the continued existence of the species. For the likely to jeopardize determinations the Service provided "reasonable and prudent alternatives" that preclude jeopardy but still allow use of the rodenticide. These alternatives represent the Service's best professional judgement of the measures necessary to provide the appropriate level of protection to the species. The Service also provided "incidental take" statements and "reasonable and prudent measures" to minimize take. Difethialone, first registered in 1995, is not addressed in this or any subsequent Biological Opinion, but EPA believes the jeopardy determinations for brodifacoum also would be applicable to difethialone. The Service's determinations for each rodenticide are tabulated below. Only the common names of the species are presented in the table for each rodenticide, but scientific names are listed in a final table. Species not included in the tables were presumed by the Service to not be affected by the rodenticide of concern or to have no chance for exposure.

Brodifacoum

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which brodifacoum "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Salt marsh harvest mouse Fresno kangaroo rat	Prohibit use within 100 yards of these species' occupied habitat
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
Audubon's crested caracara	Prohibit use within this species' occupied habitat
San Clemente loggerhead shrike	Prohibit use on San Clemente Island, California

Brodifacoum

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which brodifacoum "is not likely to jeopardize" their continued existence:	
Giant kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Point Arena mountain beaver	Incidental take can be minimized by prohibiting outdoor use within 100 yards of these species' occupied habitat
Louisiana black bear	Incidental take can be minimized by prohibiting use within occupied habitat
San Joaquin kit fox	Incidental take can be minimized by requiring that outdoor applications be made in tamper-resistant bait boxes placed in areas not accessible to wildlife
Hawaiian hawk	Incidental take can be minimized by prohibiting use within 100 yards of this species' occupied habitat
Eastern indigo snake	Incidental take can be minimized by conducting laboratory studies using surrogate snake species to obtain toxicity data on the chemical's secondary poisoning hazard to snakes

Bromadiolone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which bromadiolone "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Salt marsh harvest mouse	Prohibit use within 100 yards of these species' occupied habitat
Species for which bromadiolone "is not likely to jeopardize" their continued existence:	
Fresno kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Point Arena mountain beaver	Incidental take can be minimized by prohibiting outdoor use within 100 yards of these species' occupied habitat

Bromadiolone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
San Joaquin kit fox	Incidental take can be minimized by requiring that outdoor applications be made in tamper-resistant bait boxes placed in areas not accessible to wildlife

Chlorophacinone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which chlorophacinone "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Stephen's kangaroo rat Amargosa vole Hualapai Mexican vole	Prohibit use within 100 yards of these species' occupied habitat
Salt marsh harvest mouse Tipton kangaroo rat Giant kangaroo rat Fresno kangaroo rat Point Arena mountain beaver	Prohibit outdoor use within 100 yards of these species' occupied habitat unless specific programs for chlorophacinone are approved by the Service and implemented
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
San Joaquin kit fox	Prohibit use within the kit fox range as determined by the Service, except for agricultural areas $\geq$1 mile from any kit fox habitat as determined by the California EPA in consultation with the Service, or areas where applicable surveys have been conducted and yielded negative results

Chlorophacinone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Florida panther	Prohibit use within 20 miles of the boundary of any Federal and State lands (e.g., National Wildlife Refuge, National Park, State Park, etc.) and Indian Reservations that provide suitable panther habitat south of Charlotte, Glades and Martin counties, Florida; incidental take can be minimized by removing and properly disposing of any dead or incapacitated animal likely to have been poisoned within and including the area extending 5 miles from the edge of the prohibited use zone
Jaguarundi Ocelot	Prohibit use within 3 miles of occupied habitat; incidental take can be minimized by conducting surveys prior to use to determine if habitat is occupied
Audubon’s crested caracara	Prohibit use within this species’ occupied habitat
Species for which chlorophacinone "is not likely to jeopardize" their continued existence:	
Louisiana black bear	Incidental take can be minimized by prohibiting use within occupied habitat
Grizzly bear Gray wolf Utah prairie dog	None specified
Puerto Rican boa Virgin Island tree boa	Incidental take can be minimized by prohibiting use within the known occupied habitat
Eastern indigo snake	Incidental take can be minimized by conducting laboratory studies using surrogate snake species to obtain toxicity data on the chemical’s secondary poisoning hazard to snakes

Diphacinone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which diphacinone "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Key Largo cotton mouse Key Largo woodrat Southeastern beach mouse Morro Bay kangaroo rat Stephen's kangaroo rat Silver rice rat Hualapai Mexican vole Utah prairiedog	Prohibit use within 100 yards of these species' occupied habitat
Salt marsh harvest mouse Tipton kangaroo rat Giant kangaroo rat Fresno kangaroo rat Point Arena mountain beaver	Prohibit outdoor use within 100 yards of these species' occupied habitat unless specific programs for diphacinone are approved by the Service and implemented
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
San Joaquin kit fox	Prohibit use within the kit fox range as determined by the Service, except for agricultural areas $\geq$1 mile from any kit fox habitat as determined by the California EPA in consultation with the Service, or areas where applicable surveys have been conducted and yielded negative results
Florida panther	Prohibit use within 20 miles of the boundary of any Federal and State lands (e.g., National Wildlife Refuge, National Park, State Park, etc.) and Indian Reservations that provide suitable panther habitat south of Charlotte, Glades and Martin counties, Florida; incidental take can be minimized by removing and properly disposing of any dead or incapacitated animal likely to have been poisoned within and including the area extending 5 miles from the edge of the prohibited use zone

Diphacinone

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Jaguarundi Ocelot	Prohibit use within 3 miles of occupied habitat; incidental take can be minimized by conducting surveys prior to use to determine if habitat is occupied
Gray wolf Grizzly bear	Prohibit use within the geographic range of this species until the Service has determined the species is not in the vicinity of the treatment site
Louisiana black bear	Prohibit use within the current known occupied habitat
Black-footed ferret	Prohibit use within 7 km (4.34 mi) from a prairie dog town, except for black-tailed prairie dog colonies <80 acres in size or white-tailed prairie dog colonies <200 acres in size, or urban situations, or colonies that have been surveyed in coordination with the Service and determined that ferrets are absent
Lower Keys rabbit	Prohibit use within 100 yards of this species' occupied habitat
Audubon's crested caracara	Prohibit use within this species' occupied habitat
Species for which diphacinone "is not likely to jeopardize" their continued existence:	
Delmarva fox squirrel	Incidental take can be minimized by placing bait in bait boxes small enough to exclude fox squirrels
Puerto Rican boa Virgin Island tree boa	Incidental take can be minimized by prohibiting use within the known occupied habitat
Eastern indigo snake	Incidental take can be minimized by conducting laboratory studies using surrogate snake species to obtain toxicity data on the chemical's secondary poisoning hazard to snakes

Warfarin

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which warfarin "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Salt marsh harvest mouse Fresno kangaroo rat	Prohibit use within 100 yards of these species' occupied habitat
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
Species for which warfarin "is not likely to jeopardize" their continued existence:	
Giant kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Point Arena mountain beaver	Incidental take can be minimized by prohibiting outdoor use within 100 yards of these species' occupied habitat

Bromethalin

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which bromethalin "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat	Prohibit use within 100 yards of these species' occupied habitat
Salt marsh harvest mouse Fresno kangaroo rat	Prohibit use within 100 yards of these species' occupied habitat
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida

Bromethalin

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which bromethalin "is not likely to jeopardize" their continued existence:	
Giant kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Point Arena mountain beaver	Incidental take can be minimized by prohibiting outdoor use within 100 yards of these species' occupied habitat

Zinc phosphide

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which zinc phosphide "is likely to jeopardize" their continued existence:	
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Silver rice rat	Prohibit use within 100 yards of these species' occupied habitat
Fresno kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Giant kangaroo rat Salt marsh harvest mouse Point Arena mountain beaver	Prohibit outdoor use within 100 yards of occupied habitat unless a protection program has been approved by the Service and implemented
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
Black-footed ferret	Prohibit use within 7 km (4.34 mi) from a prairie dog town, except for black-tailed prairie dog colonies <80 acres in size or white-tailed prairie dog colonies <200 acres in size, or urban situations, or colonies that have been surveyed in coordination with the Service and determined that ferrets are absent
Hawaiian crow	Prohibit use within 100 yards of occupied habitat unless bait is placed in tamper-resistant bait boxes

Zinc phosphide

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Atwater’s prairie chicken	Prohibit use within 100 yards of occupied habitat unless bait is placed in tamper-resistant bait boxes
Hawaiian coot Hawaiian duck	Prohibit use within 100 yards of any water or wetland on or adjacent to any golf course or turf farm on the islands of Kauai, Oahu, and Maui unless bait is placed in tamper-resistant bait boxes
Nene (Hawaiian goose) Mariana crow	Prohibit use in occupied habitat unless bait is placed in tamper-resistant bait boxes
Mississippi sandhill crane Puerto Rican plain pigeon Yellow-shouldered blackbird	Outdoor baiting must use tamper-resistant bait boxes within occupied habitat
Species for which zinc phosphide "is not likely to jeopardize" their continued existence:	
Gray wolf Grizzly bear	Incidental take can be minimized by applying bait in tamper-resistant bait boxes, or contacting the local Service office to ensure that these species are not in the vicinity of the treatment site
Utah prairie dog	None specified
San Joaquin kit fox	Incidental take can be minimized by requiring that outdoor applications be made in tamper-resistant bait boxes placed in areas not accessible to wildlife
San Clemente sage sparrow	Incidental take can be minimized by prohibiting use in occupied habitat unless bait is placed in tamper-resistant bait boxes
Whooping crane	Incidental take can be minimized by ensuring that cranes have not wandered into the treatment area

Cholecalciferol

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Species for which cholecalciferol "is likely to jeopardize" their continued existence:	

Cholecalciferol

Species	Reasonable and Prudent Alternatives/ Reasonable and Prudent Measures
Alabama beach mouse Choctawhatchee beach mouse Perdido Key beach mouse Anastasia Island beach mouse Southeastern beach mouse Morro Bay kangaroo rat Salt marsh harvest mouse Fresno kangaroo rat	Prohibit use within 100 yards of these species' occupied habitat
Carolina northern flying squirrel	Prohibit outdoor use within this species' occupied habitat
Florida salt marsh vole	Prohibit use within 100 yards of the landward edge of this species' habitat in Levy County, Florida
Species for which cholecalciferol "is not likely to jeopardize" their continued existence:	
Giant kangaroo rat Stephen's kangaroo rat Tipton kangaroo rat Point Arena mountain beaver	Incidental take can be minimized by prohibiting outdoor use within 100 yards of these species' occupied habitat

Species addressed in the Biological Opinion[a]:

Mammals:

Alabama beach mouse (*Peromyscus polionotus amnobates*)

Amargosa vole (*Microtus californicus scirpensis*)

Anastasia Island beach mouse (*Peromyscus polionotus phasma*)

Black-footed ferret (*Mustela nigripes*)

Carolina northern flying squirrel (*Glaucomys sabrinus coloratus*)

Choctawhatchee beach mouse (*Peromyscus polionotus allophrys*)

Delmarva fox squirrel (*Sciurus niger cinereus*)

Florida salt marsh vole (*Microtus pennsylvanicus dukecampbelli*)

Florida panther (*Puma (=Felis) concolor coryi*)

Fresno kangaroo rat (*Dipodomys nitratoides exilis*)

Giant kangaroo rat (*Dipodomys ingens*)

Gray wolf (*Canis lupus*)

Grizzly bear (*Ursus arctos*)

Species addressed in the Biological Opinion[a]:

Hualapai Mexican vole (*Microtus pennsylvanicus hualpaiensis*)
Jaguarundi (*Herpailurus (=Felis) yagouaroundi cacomitli*)
Jaguar (*Panthera onca*)
Key Largo cotton mouse (*Peromyscus gossypinus allapaticola*)
Key Largo woodrat (*Neotoma floridana smalli*)
Lower Keys rabbit (*Sylvilagus palustris hefneri*)
Louisiana black bear (*Ursus americanus luteolus*)
Morro Bay kangaroo rat (*Dipodomys heermanni morroensis*)
Ocelot (*Leopardus (=Felis) pardalis*)
Perdido Key beach mouse (*Peromyscus polionotus trissyllepsis*)
Point Arena mountain beaver (*Aplodontia rufa nigra*)
Salt marsh harvest mouse (*Reithrodontomys raviventris*)
San Joaquin kit fox (*Vulpes macrotis mutica*)
Silver rice rat (*Oryzomys palustris natator*)
Southeastern beach mouse (*Peromyscus polionotus niveiventris*)
Stephen’s kangaroo rat (*Dipodomys stephensi*)
Tipton kangaroo rat (*Dipodomys nitratoides nitratoides*)
Utah prairie dog (*Cynomys parvidens*)

Birds:

Atwater’s prairie chicken (*Tympanuchus cupido attwateri*)
Audubon’s crested caracara (*Polyborus plancus audubonii*)
Hawaiian coot (*Fulica americana alai*)
Hawaiian crow (*Corvus hawaiiensis*)
Hawaiian duck (*Anas wyvilliana*)
Hawaiian hawk (*Buteo solitarius*)
Mariana crow (*Corvus kubaryi*)
Mississippi sandhill crane (*Grus canadensis pulla*)
Nene [Hawaiian goose] (*Branta (=Nesochen) sandvicensis*)
Puerto Rican plain pigeon (*Columba inornata wetmorei*)
San Clemente loggerhead shrike (*Lanius ludovicianus mearnsi*)
San Clemente sage sparrow (*Amphispiza belli clementeae*)
Whooping crane (*Grus americana*)
Yellow-shouldered blackbird (*Agelaius xanthomus*)

Reptiles:

Species addressed in the Biological Opinion[a]:

- Puerto Rican boa (*Epicrates inornatus*)
- Virgin Island tree boa (*Epicrates monensis granti*)
- Eastern indigo snake (*Drymarchon corais couperi*)

Wyoming County Commissioners Association
PO Box 86
Cheyenne, WY 82003

Dear Wyoming County Commissioners Association:

I wanted to personally thank you for hosting the recent tour on Thunder Basin National Grasslands. The opportunity to view the situation in person, as well as being able to engage with some of the Permittee's directly, was extremely valuable and has helped us to lay the groundwork for being able to move forward with future management on several of the issues that were identified. I also very much appreciated the participation of the permittees and the staff from the different Wyoming State Agencies. I know how valuable everyone's time is and to dedicate several days to this effort clearly demonstrates the level of concern that exists.

As we discussed, the Regional Office has worked with the Forest and District to identify both short term and long term work to be completed. The following is the current list of actions that we have identified:

Short Term Actions:

- No dusting for plague control will occur this season on federal lands within the Grassland.
- The Forest will increase acres treated this year for Prairie Dog control focusing on the boundary areas and the identified buffers around dwellings.
- The Regional Office is working with the Forest to identify maximum flexibility for options such as supplemental feeding, restoration work to aid in the recovery of impacted areas, invasive species control (cactus, etc).
- The Regional Office is looking into the appropriate use of Rozol on Forest Service lands in Thunder Basin.

Long Term Actions:

- The Regional Office is reviewing options for a potential management plan amendment regarding Black Footed Ferrets. The assessment will include the level of NEPA required, timeline, and staffing needs.

This is by no means a complete list of the work we will be carrying out, but it does reflect the majority of the areas that we discussed during the tour. Please accept my sincere appreciation for your commitment to working with us on these issues and for allowing us the opportunity to redeem our responsibility to all of you that operate on Thunder Basin and to the lands that we have been given responsibility for managing. Together I know we can get to a better place.

Sincerely,

Brian Ferebee

BRIAN FEREBEE
Regional Forester

The role of herbivores in Great Plains conservation: comparative ecology of bison and cattle

Brady W. Allred,[1],† Samuel D. Fuhlendorf,[1] and Robert G. Hamilton[2]

[1]*Natural Resource Ecology and Management, Oklahoma State University, Stillwater, Oklahoma 74078 USA*
[2]*The Nature Conservancy Tallgrass Prairie Preserve, Pawhuska, Oklahoma 74056 USA*

Abstract. The Great Plains of North America evolved with significant influence from bison (*Bison bison*), but is presently dominated by cattle (*Bos taurus*). While there are a variety of opinions concerning differences between these two species, there is a lack of scientific comparisons, including those that incorporate important ecological variation. We developed a framework to study and compare the grazing behavior and effects of bison and cattle within grassland ecosystems. Environmental (e.g., resource distribution, disturbance) and animal (e.g., number, social organization) factors play a critical role in determining grazing effects and should be incorporated into discussions that compare the effects of bison and cattle. Using this framework we specifically compare the grazing behavior of both species in tallgrass prairie and discuss the implications of these differences in the context of conservation. We collared bison and cattle with global positioning systems and used resource selection functions to estimate the importance of various environmental factors on site selection. Both species preferred recently burned areas and avoided steeper slopes. Cattle selected areas that were closer to water, while bison were not limited by distance to water; cattle also preferred areas with woody vegetation, while bison avoided them. Incorporating broad scale environmental complexity allows for an effective comparison of ecological differences between bison and cattle. While there are similarities and differences in these species, a comprehensive analysis of all conditions and scenarios is not possible. It is clear, however, that the greatest differences between these species will likely be evident from broad scale studies across complex landscapes. In addition to species, conservation and land managers need to consider other environmental factors that are critical to grazing effects and overall conservation.

Key words: fire; grassland; grazing; herbivory; restoration; species comparisons; tallgrass prairie.

INTRODUCTION

The role of herbivores in grassland ecosystems has been an important topic debated by ecologists and ecosystem managers for more than a century. The Great Plains of North America are central to this discussion as most flora and fauna evolved with significant impact from large herbivores and other disturbances (Axelrod 1985, Anderson 2006). Until their near extirpation in the late 1800s, American Bison (*Bison bison*) were keystone herbivores within the Great Plains, sharing complex landscapes with other herbivores and predators for nearly 10,000 years (Knapp et al. 1999, Anderson 2006). Since their near extinction, the vast and complex landscapes that contained the roaming herds have been replaced by fragmented agricultural lands where domestic cattle are the dominant grazers. Restoration and conservation of bison has been pursued by private citizens, conservation organizations, and government agencies with a primary goal of conserving the species and restoring critical ecosystem processes and functions.

Grazing by large herbivores can affect a system in many different ways (Milchunas et al. 1988, Augustine and McNaughton 1998, Anderson et al. 2006). The effects of grazing are often viewed in isolation of each other, removing all complexity and variation besides that of grazing. Such work has enhanced the understanding and management of grasslands. The evolutionary effects of grazing, however, are much more complex than traditional, small scale experimental designs can replicate (Levin 1992, Fuhlendorf et al. 2009). Grazing is a dynamic process that interacts with complex landscapes to form disturbance patterns that are critical to many ecosystem functions, including biodiversity (Collins et al. 1998, Tews et al. 2004). Because of this, the effects of grazing are influenced by many factors, including those associated with animals and the environment.

The species of animal alone is not the only determinant of grazing effects. Age, sex, number, and social organization of animals contribute to altering behavior and ecological influences. In addition to the structure of the grazer community, environmental factors (e.g., disturbances, climate, predation, resources) will also contribute to grazing effects. When discussing grazing or grazing behavior, a traditional reductionist approach is to focus on one factor without considering the complexity of other factors. In the Great Plains of North America, ecologists, conservation biologists, and land managers have studied and debated the effects of grazing by bison and domestic cattle (*Bos taurus*), often without including other interacting factors (Hartnett et al. 1997, Steuter and Hidinger 1999). Common managerial differences associated with bison and cattle also confound differences in effects between the two species (Towne et al. 2005). Cattle herds are often associated with ranches that are based on commodity production, where animals are commonly separated for most of the year based on sex or age (e.g., cows and calves, bulls). In the Great Plains of North America, cattle are rarely, if ever, managed as wildlife or with a conservation focus. Bison, on the other hand, may be managed as either production or conservation herds.

While similarities and differences between cattle and bison are widely discussed and debated, the peer reviewed literature comparing the two is largely inconclusive. For example, in popular press, government reports, and scientific literature, it is often stated that bison spend less time near water or riparian areas than cattle (Manning 1995, Hartnett et al. 1997, Fritz et al. 1999, Reynolds et al. 2003, National Park Service 2009). Indeed, van Vuren (1982) found a greater percentage of observations of cattle closer to water than bison. Unfortunately, it is apparent that the confounding management strategies of the two species were not taken into account, specifically with regard to stocking rate or animal density: "a herd of about 300 wild bison . . . shares its summer range with several hundred range cattle" (van Vuren 1982). With no clear definition of how many animals were present or specific management plans for each species, a reliable conclusion cannot be made. Direct comparisons of foraging ecology or behavior between bison and cattle have also been minimal. Plumb and Dodd (1993) found that in general, bison spent less time feeding with shorter grazing bouts than cattle, but had greater number of bouts per day.

We argue that recognizing ecological differences between bison and cattle would be best studied on large, complex landscapes that do not limit behavior to finer scales (Holland et al. 2004, Boyce 2006, Bowyer and Kie 2006). Incorporating landscape variability will allow for a more effective comparison of grazing behavior and effects between bison and cattle, as animals can interact with environmental factors that contribute to grazing effects. We describe the design, results, and limitations of a current study comparing bison and cattle behavior on complex landscapes that include other disturbances (e.g., fire). We then develop a conceptual model to facilitate the discussion of the conservation value of reintroducing bison within human dominated landscapes of the Great Plains.

METHODS

The Tallgrass Prairie Preserve: a model for experimental design

The Nature Conservancy Tallgrass Prairie Preserve, located in northeast Oklahoma, USA, is a 16,000 ha natural area that is managed for biodiversity and heterogeneity (Hamilton 2007). The preserve lies at the southern end of the Flint Hills of the Great Plains. Vegetation is classified as tallgrass prairie, with small patches of cross timbers forest. Dominant grasses include *Andropogon gerardii* Vitman, *Schizachyrium scoparium* (Michx.) Nash, *Panicum virgatum* L., and *Sorghastrum nutans* (L.) Nash. Crosstimbers vegetation is dominated by *Quercus stellata* Wang. and *Q. marilandica* Münchh. Precipitation and various climate measurements are measured on site by an Oklahoma Mesonet station (Brock et al. 1995). Total precipitation for April through September for 2009 and 2010 (time period of study) was 64.7 and 72.5 cm, respectively. Long term mean total for April through September is 62.2 cm (14.94 standard deviation).

Within the site, there is one large bison unit (9532 ha) and seven smaller cattle units (430–980 ha) (Fig. 1). Only perimeter fences are present and animals are free to roam within their respective units. There is minimal handling of both bison and cattle with no supplemental feeding. Bison are maintained in their respective unit all year; herd size is approximately 2,300 animals. Sex ratio of the bison herd is approximately seven females per male; ages of females range from 0–10 years, while males are 0–6 years. Cattle units are stocked with stocker steers approximately one year old (mixed European breeds); cattle are only present April through September. Cattle herds vary with each unit, ranging from 169 to 463 animals. Bison and cattle units are stocked with similar moderate stocking rates (bison: 2.1 AUM/ha; cattle: 2.4 AUM/ha). The entire preserve is managed extensively with fire and in such way that fire and grazing are allowed to interact (Hamilton 2007, Fuhlendorf et al. 2009). Bison and cattle units are shifting mosaics with fire occurring in discrete portions of the landscape (Fig. 1). Fire-grazing interactions become present as animals select between recently burned areas and those with greater time since fire (Archibald et al. 2005, Fuhlendorf et al. 2009).

To specifically examine herbivore site selection, we deployed global positioning system (GPS) collars on seven female bison (four to six years in age) from November 2008 through November 2010 and seven cattle (steers, one year in age; one per unit) from April through September of 2009 and 2010. For bison, GPS batteries were replaced and new animals chosen in November 2009; for cattle, new animals were chosen and new batteries used in April 2010. We recorded location information of animals at two different frequencies, alternately weekly from 12 minutes to one hour. Schedule of GPS fixes was equal for bison and cattle. We imported all GPS location data into a spatially enabled database (PostgreSQL/PostGIS) and reduced bison data to match that of cattle (April–September). We mapped treatment unit perimeters, fire histories, and water sources (ponds and streams) with handheld GPS units, aerial photographs, and United States Geological Survey 7.5 minute topographic maps. Slope and aspect were calculated from digital elevation models for the area (United States Geological Survey; 10 m resolution). We transformed aspect data by simple trigonometric functions; two variables were created, northing = cosine(aspect) and easting = sin(aspect). Herbaceous and woody vegetation was determined for the site using a GeoEye-1 satellite image acquired September 20, 2009.

We compared similarity of units by randomly placing 1,000 sampling points within each unit. At each sampling point, distance to water, distance to patch edge, distance to woody vegetation, slope, northing, and easting were calculated. Measured characteristics among animal units were compared individually using analysis of variance and did not differ between units ($P > 0.05$). We used Ivlev electivity indices (Ivlev 1961, Jacobs 1974) to evaluate the use of riparian areas by bison and cattle. Riparian areas were defined by putting a 20 and 40 m buffer around all mapped water sources. We calculated electivity indices using the formula $E_i = (r_i - p_i)/(r_i + p_i)$ where r_i is the fraction of GPS locations recorded in a riparian area by animal i and p_i is the fraction of area enclosed by the sum of buffers available to animal i. A value of +1 indicates complete preference to riparian areas, while a value of −1 indicates complete avoidance. Indices were calculated for each collared bison

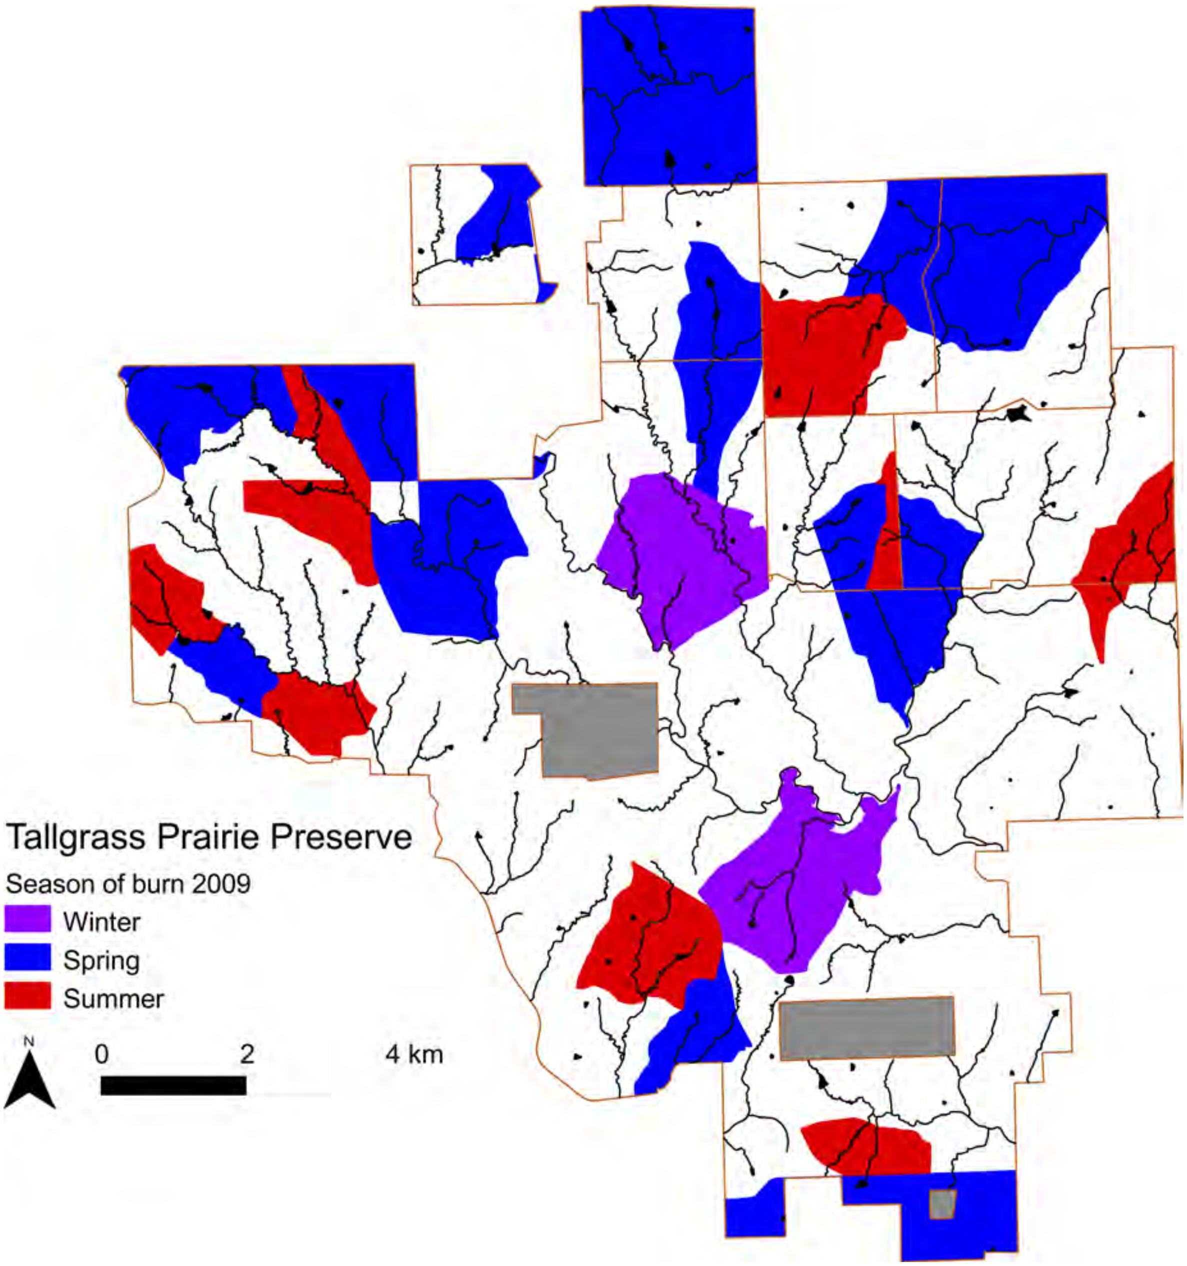

Fig. 1. Map of prescribed fire and water distribution within bison and cattle units at The Nature Conservancy Tallgrass Prairie Preserve, OK, USA, September 2009. Solid orange lines represent perimeter fences and delineate units. Black interior lines and areas represent water sources. Gray areas inside bison unit represent inholdings which bison cannot access. The large southern unit is 9532 ha in size and contains bison year round. The northern units are 430–980 ha in size and contains mixed European breeds of cattle April-September. Differing colors represent season of burn for 2009 and illustrate the patchiness of fire. Patches from previous years are not shown, but vary from one to five years since fire. Grazing animals have free access to all burns within their respective units (no internal fences present).

and cattle individual, separating water sources into ponds, streams, and pond/stream combination. Indices between bison and cattle were compared for each size riparian area (i.e., 20 and 40 m) using a *t*-test. We also used Ivlev electivity indices to compare bison and cattle preferences for recently burned areas (six months or less since fire). We calculated indices for each collared animal based upon recently burned area available; we compared indices using a *t*-test.

To examine the influence of environmental factors on the grazing behavior of bison and cattle, we estimated resource selection functions using mixed-effect logistic regression models (used/available design; Boyce et al. 2002, Manly et al. 2002). To depict available habitat, we created five random locations for each observed location. We calculated the amount of time since fire, distance to water, distance to fire patch edge, slope, northing, and easting for all locations. We also classified each location as herbaceous or woody vegetation. To determine if the presence of woody vegetation is confounded with water sources (i.e., the presence of woody vegetation is primarily near water sources), we quantified the distribution of woody vegetation around water sources. The percentage of woody vegetation within 20 and 40 m of water sources across the site was 3% and 7%, respectively. Furthermore, we examined variables for collinearity and found none ($r^2 < 0.27$ for all variable combinations), indicating that variables are not confounding with one another (i.e., woody vegetation is not limited near water sources). To account for variation among individual animals within resource selection functions, individuals were included as a random intercept within logistic regressions. To account for fire availability among units and potential response variation to fire, time since fire and its interaction with other variables (e.g., time since fire × distance to water; see below) were included as random slopes within logistic regressions (Gillies et al. 2006).

We created models using various combinations of environmental factors; as the influence of time since fire is likely to be highly influential (Vinton et al. 1993, Fuhlendorf and Engle 2004, Archibald et al. 2005), we included interaction terms for this variable with all others individually (i.e., time since fire × distance to water, time since fire × slope, etc.). In all models with interaction terms, main effects of both variables were included. To allow for comparison of environmental factors and to more easily interpret interaction terms, we standardized variables by subtracting the mean and dividing by the standard deviation (Gelman and Hill 2007). We compared and ranked models using Akaike information criterion (AIC; Burnham and Anderson 2002). We used bootstrapping procedures to further estimate the precision of resource selection coefficients of the top ranked model. We calculated 95% confidence intervals of coefficients after 1,000 iterations of randomly sampled datasets. To further examine variation among individual animal behavior, we calculated resource selection functions for each animal per year (28 animals total) using top ranked models. We performed all analyses in R (R Development Core Team 2009) with additional use of the *lme4* (Bates and Maechler 2010), *doMPI* (Weston 2009), *foreach* (Revolution Computing 2009) and *Rmpi* (Yu 2010) packages.

RESULTS

Of bison locations, 9 and 15% fell within riparian areas of size 20 and 40 m, respectively (ponds and streams combined). Of cattle locations, 13 and 20% fell within riparian areas of size 20 and 40 m, respectively. Mean Ivlev electivity indices of riparian areas varied significantly between bison and cattle with all water sources and riparian area sizes ($P < 0.01$; Fig. 2). Cattle had a greater preference for ponds (Fig. 2A), while bison avoided streams (Fig. 2B). When ponds and streams were combined, bison had a small avoidance of water, while cattle had a greater preference for it (Fig. 2C). These data show the difference between bison and cattle in their use of water and riparian areas, in similar fire-managed landscapes with abundant water.

Bison and cattle strongly preferred recently burned patches (Table 1). Mean percentages of GPS locations in areas with six months or less since fire did not vary between bison and cattle ($P = 0.11$) With bison, 68% of locations were found in recently burned areas (less than six months), while cattle were 58%. The amount of area burned within six months was approximately 25% of the landscape in both bison and cattle units. Bison and cattle were nearly three times likely to be in a burned area than by random

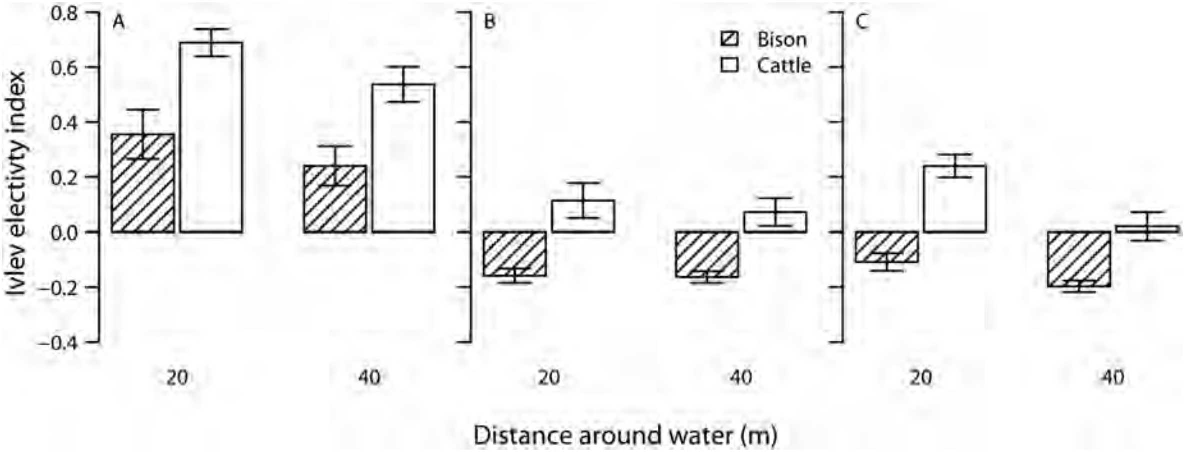

Fig. 2. Ivlev electivity indices for riparian areas, separated by bison and cattle at the Tallgrass Prairie Preserve, OK, USA. Bars are means (n = 14; animals), error bars are one standard deviation. Potential values range from −1 (complete avoidance) to +1 (complete preference). Distance around water indicates the size of buffer placed around water sources. A) Ivlev electivity indices for ponds only, separated by bison and cattle. Cattle preferred riparian pond areas more than bison. B) Ivlev electivity indices for streams only, separated by bison and cattle. Cattle preferred riparian stream areas more than bison; bison demonstrated a small avoidance to riparian stream areas. C) Ivlev electivity indices for ponds and streams combined, separated by bison and cattle. Cattle preferred all riparian areas more than bison; bison demonstrated a small avoidance to all riparian areas. Mean electivity indices of riparian areas varied significantly between bison and cattle for all water sources and buffer sizes ($P <$ 0.01).

chance alone. Mean Ivlev electivity indices of recently burned areas were 0.57 (0.01) and 0.43 (0.15) for bison and cattle, respectively (standard deviations in parentheses); indices did not differ between species ($P = 0.12$).

Estimation of resource selection functions permitted a detailed examination of environmental factors that influence selection behavior. Of models examined, the combination of interaction terms of time since fire with all variables (less northing and easting) appeared to have the best fit for both bison and cattle (Table 2). Resource selection functions for bison revealed that time since fire had the strongest influence in determining site selection. Furthermore, bison tended to avoid steeper slopes and wooded areas. Distance to water did not influence selection (Table 3). Interactions of time since fire with other environmental factors indicates the connectedness of fire with grazing behavior. The influence of time since fire increased as slope and distance to patch edge increased; conversely, the influence

of time since fire decreased as woody vegetation and distance to water increased. This decrease is minimal due to the initial strong influence of fire. The probability of selection for bison, based upon time since fire, distance to water, and the interaction of those two factors, is displayed in Fig. 3. In recently burned areas, bison avoid water slightly; in areas with greater time since fire, bison are not influenced by water.

Similar to bison, cattle also selected recently burned areas and avoided steeper slopes. Unlike bison, however, the most influential environmental factor was the preference of woody vegetation. Moreover, cattle appeared to minimize distance to water, opposite that of bison (Table 3). Interactions of time since fire with other variables further shows the importance of fire to understanding grazing within these ecosystems. As distance to water and patch edge increase, so does the influence of time since fire; the presence of woody vegetation, however, decreases the influence of time since fire. The probability of selection for cattle, based upon time since fire, distance to water, and the interaction of the two, is displayed in Fig. 4. Cattle minimize their distance to water in both recently burned areas and areas with greater time since fire.

Resource selection functions for individual animals revealed variation in site selection (Table 4). Though individual animals generally followed trends indicated by the population model, cattle tended to be more variable in their response to environmental factors. Individual bison and cattle still strongly preferred recently burned areas (minimizing the amount of time since fire), but the response of cattle varied considerably among individuals. All individual cattle minimized their distance to water, while only three bison did so. Other factors, including interactions with time since fire, varied among animals. Because different animals were chosen each year, we cannot separate the variation among animals and the variation between years.

Discussion

The design of this study more effectively permits comparisons between bison and cattle, both in examining grazing behavior differences between the species (results presented here) and their ecological effects (e.g., plant response, water quality, etc.; data not collected). Our design incorporates more of the variability found in complex landscapes than previous studies, allowing animals to interact and respond to variation and complexity across the landscape. Bison and cattle had similarities in some aspects of their behavior. Both species had a strong preference for recently burned areas, similar to separate studies of the individual species (Coppedge et al. 1998, Fuhlendorf and Engle 2004). Along with similarities we also identified two key differences. Cattle preferred areas with woody vegetation, while bison avoided them. This likely plays a critical role in thermal regulation, with woody canopy cover providing shade from solar radiation. Detailed mapping of the thermal environment is required to determine the influence of heat on the grazing behavior of bison and cattle. Additionally, because location information obtained by the GPS does not differentiate between grazing or resting, it is unclear if the preference for woody vegetation is a result of grazing or resting behavior. It does show, however, behavioral preferences and differences that are likely to influence both selection and grazing decisions, especially when studying behavior at broad spatial scales.

Selection for sites closer to water was also greater in cattle than bison; bison appeared to maximize their distance to water while cattle minimized it. These differences occurred in a well watered landscape and may be even more important in lands with greater distance between water sources. Though water included ponds and streams, ephemeral water sources were not included due to difficulty in measuring them at this spatial scale. Differences in use of ephemeral water between bison and cattle may explain measured differences. Additionally, both bison and cattle distribution and behavior may be influenced by precipitation patterns (Lott 2002, McAllister et al. 2006). At broader scales such as the Tallgrass Prairie Preserve, variability in spatial precipitation patterns may exist (Augustine 2010). Though not quantified, spatial variability in precipitation would likely influence animal distribution indirectly through vegetation responses and ephemeral water sources.

Although we did not collect data on ecological implications of grazing, it is likely that distribution differences between bison and cattle would

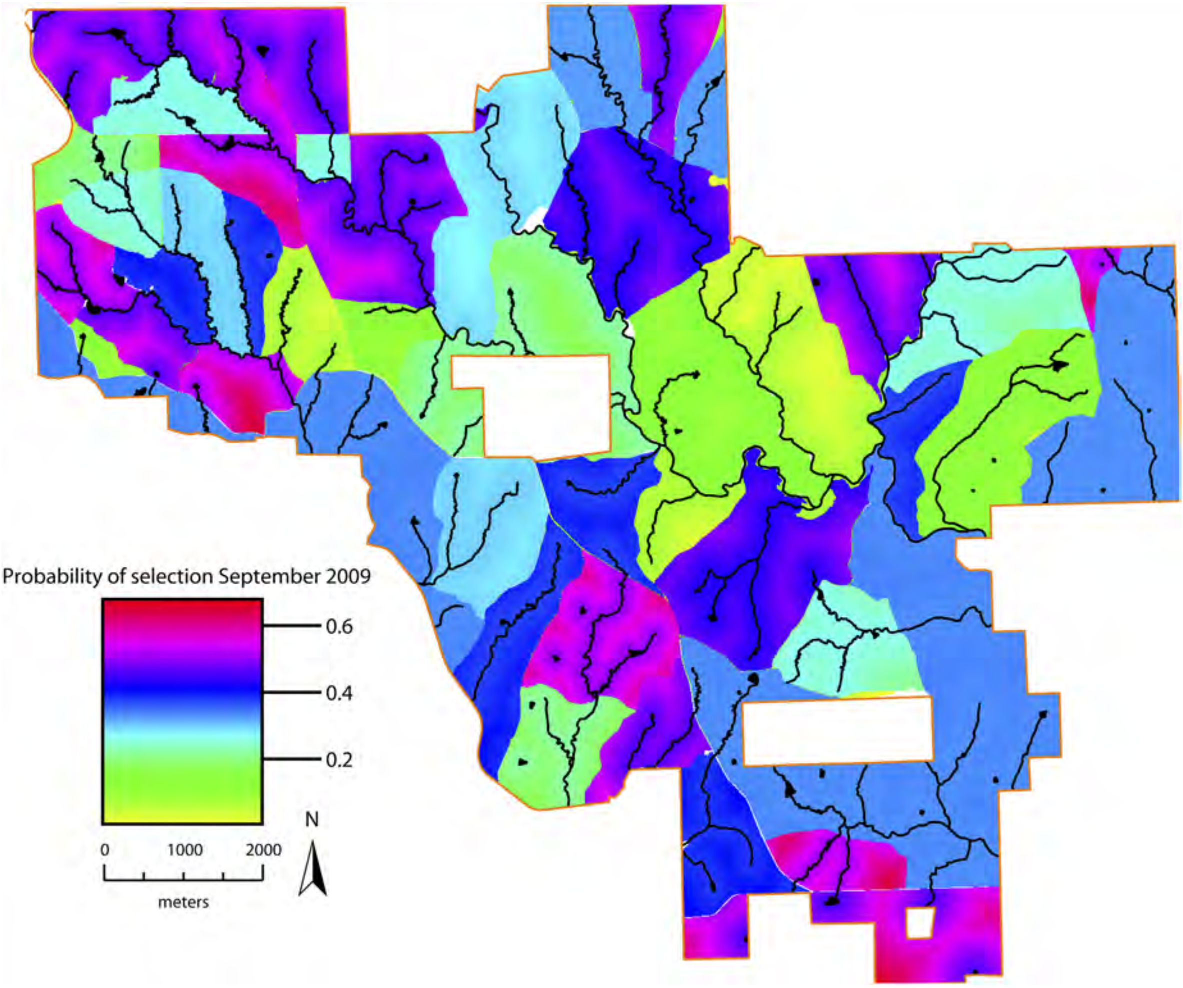

Fig. 3. Probability of selection for bison at the Tallgrass Prairie Preserve, OK, USA September 2009. Probabilities presented as a function of time since fire, distance to water, and their interaction. Black interior lines and areas represent water sources. Solid orange lines represent perimeter fences. Refer to Fig. 1 for recently burned areas. Bison prefer recently burned areas and do not minimize their distance to water. Due to the preference of recently burned areas, probabilities will change as fire is applied and moved around the landscape.

result in contrasting effects. The preference or focusing of grazing in a particular area (large or small) will influence vegetation community and characteristics. The continued attraction of both bison and cattle to recently burned areas alters vegetation structure which affects biodiversity (Fuhlendorf et al. 2006), fire behavior (Leonard et al. 2010), invasive species populations (Cummings et al. 2007), invertebrate populations and communities (Engle et al. 2008), and nutrient cycling and distribution (Anderson et al. 2006). The preference of riparian and woody vegetation areas by cattle will also likely result in vegetation and system changes. Reduced herbaceous cover, biomass, and productivity generally result from cattle grazing within riparian areas (Kauffman et al. 1983, Clary 1995, Belsky et al. 1999). Preference for water sources may also affect stream bank morphology, hydrology, and water quality (Kauffman and Krueger 1984, Trimble and Mendel 1995, Belsky and Blumenthal 1997). Concentration of livestock around ponds and streams may also likely increase nutrient concentrations (Schepers and Francis 1982, Belsky et al. 1999). We note, however, that direct comparisons of bison and cattle grazing effects on riparian

processes are largely lacking.

It is difficult to account for the many factors that may create differences or similarities between bison and cattle, and like all studies of processes on complex landscapes, this study is not without limitations. Though stocking rates were similar between bison and cattle units, cattle were only present during the growing season (April–September), while bison remained throughout the year. Differences in the social and temporal organizations of cattle and bison herds may also confound differences. The bison herd was a mixture of males and females of various ages grazing together, while cattle herds were yearling stocker steers. A yearlong, cow-calf cattle operation would permit even better comparisons between the two species, particularly with regard to ecological effects. Though treatment units were large and incorporated landscape complexity, they were not of equal size. We could expect that animal behavior would be sensitive to and vary with available area. Smaller units would limit animal movement and behavior, restricting selection and interaction with other environmental factors. Available area would be important particularly regarding cattle preference for water, as smaller units would constrain animals closer to water. While cattle

†Standardized variables are shown for coefficient comparison and interaction term interpretation.
‡Variation measured by calculating the standard deviation of coefficients within species.

units within the Tallgrass Prairie Preserve are smaller than the bison unit, they are larger than the majority of land holdings within the Great Plains; size likely did not limit the distance to water. This study also compared bison to European cattle breeds that are typical for livestock production objectives on tallgrass prairies. Other breeds of cattle are likely to respond differently (Rook et al. 2004, VanWagoner et al. 2006). Brahman or Texas longhorn breeds, for example, are likely to be adapted to more arid environments where water is limiting and may behave more similarly to bison.

In the Great Plains of North America, bison are reintroduced for primarily two objectives: species conservation and restoration of ecosystem processes. Reintroduction to conservation areas, development of private herds, and recent efforts in identifying pure herds to conserve genetics have been successful in restoring wild bison populations to many areas. Conservation of this species is a unique success story that deserves acknowledgement. Bison are also reintroduced to restore keystone effects (Knapp et al. 1999). Conservation groups as well as government agencies reintroduce bison to both small prairie remnants and large landscapes to restore historical disturbance patterns. In most cases, this is done without considering the many other factors that influence grazing behavior or effects. While the first objective for reintroduction can be accomplished by building up bison herds throughout the Great Plains, the second objective is not possible without the consideration or reintroduction of other environmental or animal factors. For example, we show that both of these herbivores have a strong preference for recently burned areas. This may suggest that the reintro-

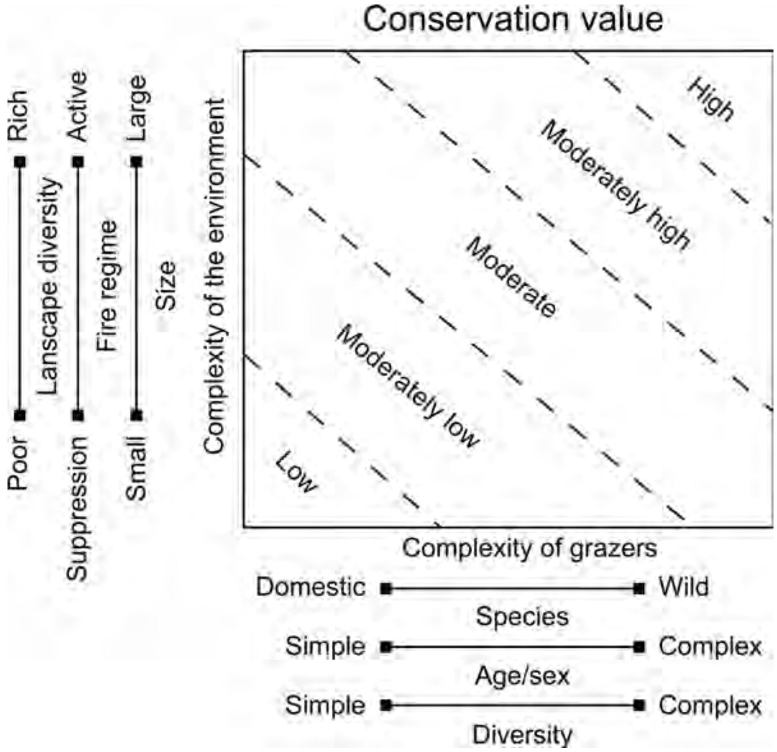

Fig. 5. Conceptual model to evaluate conservation value with respect to animal and environmental factors. Conservation value is defined as the contribution to regional conservation efforts, which includes the promotion of native plants, animals, and ecosystem processes. Species of animal alone does not automatically increase the value in regard to conservation; other factors play an important role in overall conservation value.

duction of bison, or the evaluation of differences between these species, may be largely irrelevant unless fire and other complexities are incorporated (Fuhlendorf et al. 2009). It is likely true that other factors, such as predators, would also greatly alter animal behavior and grazing effects (Ripple and Beschta 2003).

Conservation efforts regarding bison reintroduction should be evaluated to not only see if specific objectives are met, but how efforts contribute to overall conservation. We developed a conceptual model to evaluate the conservation value of different options regarding bison reintroduction (Fig. 5). We define conservation value as the contribution to regional conservation efforts, including promotion of native plants, animals, and ecosystem processes. The model is based on two primary factors that influence grazing behavior and effects, primarily complexity of grazers and the environment. Complexity of grazers refers to factors such as species, diversity, and social organization that contribute to the overall conservation value. Although this study examined only differences between two species, increasing species diversity with multiple species will add additional complexity to the system and alter the effects of grazing (du Toit and Cumming 1999, Hooper et al. 2005, Burns et al. 2009). Other native species in North American grasslands, such as prairie dogs (*Cynomys* spp.) are also important components of the system; as an example, incorporating prairie dogs will increase conservation value (Coppock et al. 1983).

The social organization of ungulates, particularly age and sex ratios, also contribute to ecosystem functioning, complexity, and conservation (Sheldon and West 2004, Gordon et al. 2004, Milner et al. 2007). Variation in animal factors will also contribute to interactions with the environment. For example, the body size of animals (also related to age and sex) influences preferences for burned areas, playing an important role in spatiotemporal heterogeneity (Wilsey 1996, Sensenig et al. 2010). Simple social organization, such as the yearling stocker steers within cattle units of this study, limit variability and decrease conservation value. With particular regard to livestock production, complexity of grazers may be improved by increasing individual variation or combing differing breeds or species (VanWagoner et al. 2006, Searle et al. 2010). Historically, bison were a keystone species, but their impacts were dependent upon how they interacted with the environment, disturbances, and other herbivores. Increasing the complexity of grazers (more species diversity, more wild herbivores, etc.) increases the conservation value, but this value is also dependent upon environmental factors. The simple replacement of domestic cattle with bison may contribute to bison conservation, but may have minimal impact on the broader conservation value of ecosystems. In an extreme example, replacing cattle with bison in a small, intensively managed, and simplified livestock production operation (e.g., a feedlot or small pasture) has little conservation value. Restoring other important processes such as fire, predation, etc. are just as important as the large herbivore upon the landscape (Ripple and Beschta 2003, Fuhlendorf et al. 2009).

Conservation value is also dependent upon the environmental complexity of the area. The majority of these factors are independent of the species of herbivore. In mesic grasslands of the Great Plains (tallgrass and mixed grass prairies), fire-grazing interactions have been shown to be a dominant driver of animal distribution and integral ecosystem process (Fuhlendorf and Engle 2004, Vermeire et al. 2004, Anderson et al. 2006). Similar to the example given above, the simple replacement of cattle with bison without a restoration of fire regimes will not result in disturbance patterns that are critical for conservation and biodiversity. In our study, time since fire was a primary driver in bison and cattle grazing behavior. The suppression of fire or the simplification of fire-grazing interactions within fire prone systems will limit conservation value, regardless of the herbivore species. Environmental factors that are critical to grazing effects and other ecosystem processes need to be accounted for in study designs that evaluate the role of grazing in conservation efforts. In North American grasslands, key environmental factors include fire regimes (Wright and Bailey 1982, Knapp et al. 1998, Brockway et al. 2002), landscape complexity and size (Herkert 1994, With et al. 2008), water distribution (Bailey et al. 1996, Augustine 2010), and woody vegetation (Archer et al. 1995, Briggs et al. 2002). These do not only influence grazing and the resulting effects, but play a broader role in ecosystem functioning. On lands with minimal environmental complexity, any differences between bison and cattle will likely contribute little to conservation value.

Grasslands are endangered worldwide (Hoekstra et al. 2005). While propositions to restore or conserve grasslands regularly focus on native herbivores (e.g., Sanderson et al. 2008), it is often overlooked that the majority of grasslands are privately owned and used for domestic livestock production (particularly true in the Great Plains of North America; Samson and Knopf 1994). Low and high conservation values can be achieved with bison or cattle. Though bison are the iconic symbol of the Great Plains of North America, and it is critical that we conserve the species, there are not enough data to confidently state that landscapes with bison are inherently better than landscapes with cattle for overall conservation or biodiversity. Both species can be mismanaged and cause degradation of habitat as well as ecological processes. Using domestic cattle to achieve some conservation objectives may be more practical or relevant, as cattle currently make up the vast majority of herbivores in many grasslands. Conservation value of productions cattle herds can be improved by increasing the size and complexity of landscape available. Allowing cattle to move at broader spatial scales and to interact with biotic and abiotic factors, may increase conservation value substantially, perhaps more so than replacing cattle with bison at finer scales. Popular management strategies that constrain animal movement and behavior (through use of fencing and rotation) may prevent many important interactions between the animal and environment, potentially reducing conservation value. As more studies effectively and appropriately compare grazing behavior and effects at broad and fine spatial scales, additional reliable conclusions will be made that may change conservation efforts or directions.

We argue that for future studies and comparisons between bison and cattle (as well as other species) it is critical that we limit our extrapolation with discussions of the abiotic and biotic environment in which these studies occur. Though it is unlikely that we will be able to conduct studies that encompass all possibilities in environmental and herbivore complexity, we must begin to contextualize our discussions and limit our inferences. From a conservation perspective it is important to understand the ecological effects of cattle grazing for livestock production, and explore approaches to alter these patterns to more effectively achieve conservation objectives. It is not productive to look for differences or similarities between bison and cattle to justify certain management objectives or agenda. In the face of the vast variability and complexity in which these species are nested within, generalizations are limited and over inferences likely.

Conservation of bison is important as an iconic species and a keystone herbivore (Knapp et al. 1999). From a broad context, however, conservation efforts need to recognize that cattle will continue to be a dominant feature on the Great Plains and grasslands worldwide, and that some conservation objectives may be met using cattle. It is critical to understand grazing behavior and ecological effects of both species in simple and complex landscapes relevant to conservation. There is an important place for species comparisons, but this is just one aspect of grassland conservation and may not be the most important for future conservation of biodiversity.

ACKNOWLEDGMENTS

We thank the staff of the Tallgrass Prairie Preserve for logistical support. We are grateful to the American Bison Society and Oklahoma Chapter of The Nature Conservancy for funding and support. We thank Dana Brunson for use and maintenance of high performance computing resources. Dwayne Elmore, Dave Engle, Eva Fearn, Curt Freese, and Kent Redford offered suggestions while preparing and writing the manuscript. David Augustine and two reviewers provided wonderful critiques and suggestions that improved the paper. We gratefully acknowledge those that develop and maintain the open source software used. B.A. thanks Angela Allred for support and encouragement.

Creating a Reserve within the Thunder Basin National Grasslands

Committee Chair: Len Broberg

This professional paper addresses the obstacles that prohibit the Thunder Basin National Grasslands of northeastern Wyoming from functioning as an ecosystem. By using the Thunder Basin National Grasslands as a model, aspects of conservation biology, economics, law, federal management practices, public land consolidation and land use reform are considered to develop a series of steps toward ecological recovery.

This examination of present conditions of the Wyoming prairie ecosystem and the series of strategies suggested for prairie recovery and preservation are meant to be universally applicable to the American Northern Plains. This paper should function as a guide for advocates and concerned individuals interested in identifying and protecting contiguous pieces of public land in the Northern Plains. Livestock grazing, roads, federal management bias and land fragmentation are discussed as current obstacles that prevent a pristine prairie ecosystem.

The recommendations presented in this paper enable the hypothetical creation of an ecological reserve within the scattered pieces of public land in Thunder Basin National Grasslands. Grassland species re-introduction, recovery efforts and recreation possibilities are presented as ecologically sound alternatives to livestock grazing and other forms of resource extraction in northeastern Wyoming.

Foreword

[The Great Plains] are wholly unfit for cultivation, and of course uninhabitable by a people depending on agriculture for their substance. Although tracts of fertile land considerably extensive are occasionally to be met with, yet the scarcity of wood and water, almost uniformly prevalent, will prove an insuperable obstacle in the way of settling this country. This is a region that seems particularly adapted to buffaloes, wild goats and other wild game; incalculable multitudes of which find ample pasturage and subsistence upon it.

(Explorer Maj. US Long, 1820)

In an effort to address the diminishing biodiversity of the Northern Plains, this paper details a series of recommendations for prairie protection. Using the Thunder Basin National Grasslands (TBNG) as a model, I will show that federal management must implement biological, legal and political remedies to protect Northern Plains regions. TBNG is an ideal study area because it provides examples of almost every problem conflicting with ecological integrity in the mixed grass prairie ecosystem on Great Plains public lands. This paper is meant to function as a guidebook. Although the following chapters tailor solutions to TBNG, the suggestions can be universally applied to the High Plains region.

The project fits into a larger effort in High Plains protection, the High Plains Ecosystem Recovery Plan (HPERP). The goal of HPERP is to identify large tracks of federal land within the High Plains region, link these lands with corridors, and create a contiguous block of public land adequate for the maintenance and re-introduction of minimum viable populations of prairie species. HPERP looks to include sections of Bureau of Land Management (BLM) lands; state lands; Native American reservation lands; National Grasslands and US Forest Service (USFS) lands; nature preserves; conservation easements; Wild and Scenic River corridors; and other suitable lands in the plains bioregion throughout Montana, Wyoming, North and South Dakota, Nebraska and Colorado.

HPERP is particularly timely. According to the socio-economic studies of sociologists, (Popper 1991) human communities within the Great Plains are currently facing an acute economic slump. Despite mining and grazing in this region, community economies in the Great Plains do not register significant earnings on a national economic grid, indicating that existing extractive industries do not support High Plains communities (Popper, 1991). So as national economics of the plains states continue to force a human depopulation trend (Popper, 1991), some original biodiversity may soon have the opportunity to reclaim former habitat.

The reality that the biosphere is driven by.....interdependence...challenges both small minds and big governments. (Judy Meyer and Gene Helfman)

Introduction

Grasslands--Going, going, gone

Men of every rank were eager to get into the cow business. In a short time every acre of grass was stocked beyond its fullest capacity. Thousands of cattle and sheep were crowded on the ranges when half the number were too many. The grasses were entirely consumed; their very roots were trampled into the dust and destroyed. In their eagerness to get something for nothing speculators did not hesitate at the permanent injury, if not the total ruin, of the finest grazing country in America.

(H.L. Bentley, 1898, somewhere on the American Plains)

The plains stretch from the Rocky Mountains eastward to meet the tallgrass prairies of Illinois, Kansas and Oklahoma. Southern prairie extends into Northern Mexico and the northern prairie extends into Canada (Brown, 1989). The northern grasslands, or High Plains, refer to shortgrass prairies that still cover much of eastern Montana, eastern and southern Wyoming, North and South Dakota, eastern Colorado and parts of Nebraska. The existing natural prairie regions of these North American states, however, are simply a small remnant of its historic extent.

A hundred years of pressure from ranching, farming and mining have damaged this ecosystem, wiping out most of the once prolific biodiversity. Without a strategy to preserve the remaining biota of the shortgrass prairie, the Northern Plains will continue to deteriorate, leaving only a giant livestock pasture.

Human impacts have resulted in significant damage to both wildlife species as well as vegetation. The coming of Europeans to the western United States created a tradition of homesteading, sodbusting and ranching , decimating the prairie's rich mosaic of grasses. As bison were wiped out, cattle and sheep overtook the grasslands. Monocultures of alfalfa, winter wheat, and crested wheatgrass, edged out many native climax species (Davis, 1994). Native species such as buffalo grass, blue grama, hairy grass, and large leaf sage were also replaced with low grade, invader species as a result of prairie deterioration (Brown, 1989).

Early in the century, in the effort to protect their defenseless livestock herds, many ranchers targeted and exterminated the plains grizzly and gray wolf from the plains. Of the large predators, only the mountain lion and the coyote still remain in the High Plains. Prairie dogs, thought to compete with livestock for forage, were also marked for extinction. Prairie dog extirpation programs, regional shooting programs, farming practices and conversion of grasslands facilitated staggering declines in prairie dog populations. (Carlton, 1994)

The prairie dog was recently petitioned by the Biodiversity Legal Foundation for endangered species listing (Carlton, 1994). Because the Black-tailed (*Cynomys ludovicianus*) and White-tailed (*Cynomys leucarus*) prairie dogs provide food and habitat (burrow) to as many as 164 associated species, as prairie dog colonies declined, many other dependent species populations followed. Some of the species adversely effected include the ferruginous hawk (*Buteo regalis*), the mountain plover (*Charadrius montanus),* the burrowing owl (*Speotyto cunicularia*) and listed endangered species, the swift fox (*Vulpes velox*) and the black-footed ferret (*Mustela nigripes*) (BLF, 1994). Species no longer found on the plains are the gray wolf (*Canis lupis),* bison (*Bison bison*) and the grizzly bear (*Ursus acrtos horribilis*).[1]

Like the entire shortgrass prairie ecosystem, the ecological state of the TBNG is degraded. Moreover, there are no current federal efforts for management reform or biotic recovery. Although TBNG has been mentioned as a re-introduction site for the black-footed ferret and bison (USFS, 1986), obstacles continue in this grassland which may prevent the survival of the ferret, bison and many other prairie species.

As it stands, the Northern prairie is in need of rescue. Although the first step to plains recovery will be to identify and challenge detrimental cultural practices, implementation of many suggestions will require legal, legislative and community outreach for successful implementation. [2]

---

[1] The Black-footed ferret is being re-intoduced to some plains regions.

[2] Outreach is essential and tricky. Community work will not be discussed in this document, but is none the less an important part of reform.

Methodology for Ecosystem Reconstruction

The northern plains of Wyoming have been targeted for intention of protection and assimilation into HPERP. The following methodology should be used as a guideline.

1) Select a region within the plains bioregion containing large sections of federal land acreage:
   - determine land ownership (federal, state, private)
   - assess patterns of mixed ownership

2) Study current uses of land
   - determine livestock numbers
   - determine mining operations
   - study files on range conditions and ranching operations

3) Study the health of the region
   - determine sensitive plant and animal species in the area
   - determine native species that are missing
   - critique federal management monitoring program for sensitive species' critical habitat, riparian areas, ecosystem integrity

4) Identify obstacles for intact ecosystems
   - determine how livestock grazing presents problems for the ecosystem
   - determine how human manipulation of the range presents ecological problems
   - examine mining efforts within the ecosystem
   - examine land fragmentation effects on ecosystem integrity

5) Classify current management practices for the region
   - examine how management creates; perpetuates; removes obstacles

preventing a complete intact prairie
- determine if management decisions include looking at the effects on all species in the ecosystem
- determine if management decisions are made with thought toward restoration and future re-introductions

6) Study federal lands and identify key private linkages between federal tracts in the context of establishing contiguous habitat with thought toward bison range and large predator ranges.

7) Consider means for federal protection of the area
- consider legal means to challenge and remove threats to ecosystem integrity
- consider means of land acquisition for linkages and critical habitat
- consider outreach into local communities

8) Consider budget and fund-raising opportunities
- assess expense of strategies and fund-raise for budget
- determine legal expenses and research *pro bono* opportunities
- determine lobbying expenses for legislative routes
- consider restoration expenses and re-introduction expenses
- contact foundations, universities and native species farms and ranches for monetary assistance, volunteer work and donations

9) Identify benefits to the region
- research how change will benefit or harm local economy
- determine if communities will be sustainable despite various subsidy cuts
- show how recreation and tourism will improve economy

10) Suggest implementation of a plan for native prairie ecosystem recovery
- present restoration goals/methods
- secure legal and legislative protection
- restore biodiversity as necessary

With these guidelines in mind, the following text discusses implementation of ecosystem recovery strategies in the TBNG.

Chapter 1

Thunder Basin National Grasslands

It would have been easier to count the leaves in the forest than it would to count the number of buffaloes living at any given time prior to 1870--(**museum curator W.T. Hornaday, 1905**)

Thunder Basin National Grasslands (TBNG), is administered by the Douglas Ranger District of the Medicine Bow National Forest in northeastern Wyoming. Bordered by the Black Hills on the east and by the Bighorn Mountains on the west, the TBNG is located within a topographic depression known as the Powder River Basin. The area contains four separate ecotypes due to variations in elevation, topography and microclimates: upland plains -- a high plateau on the western edge of the TBNG; escarpments -- eroded plains that have formed walls measuring 300-400 feet on the eastern and northeastern edges of TBNG; broken dissected plains -- a series of ridges and plains; and shale uplands -- shaley soils on the Black hills uplift that are typified by ponderosa pine growth. (USFS, 1990) To the southwest of TBNG rises Laramie Peak, a northern peak in the Laramie range.

The climate in TBNG is semi-arid, with summer temperatures exceeding 90 degrees and winter temperatures dropping below -40 degrees. Average annual rainfall is about 11 inches with snowfall constituting 1/3 of the annual precipitation. There are five vegetation types in the TBNG: grassland type -- including western wheatgrass, blue grama, needle and thread; sagebrush/grassland type -- including big sagebrush, blue grama and prickly pear; greasewood/cottonwood type -- including cottonwoods, greasewood, silver sagebrush, western wheatgrass and inland saltgrass; ponderosa pine/juniper type -- including ponderosa and juniper stands with bluebunch wheat grass, blue grama and big sagebrush; and badland type -- including sagebrush, yucca and western wheatgrass. (USFS, 1990)

Resources, Past and Present

Not even a buffalo was now in sight to relieve the dull monotony of the scene; although during some seasons, particularly fall, these prairie's are literally strewn with herds of this animals. (Early traveler to Wyoming, circa 1872)

From the late 1800's to the 1920's, many homesteaders abandoned this portion of Wyoming, finally understanding that the region was "*not suitable for cultivation of cash crops and the homesteads were too small to support successful livestock operations. Early efforts to make the land produce beyond its physical limits resulted in serious depletion of the basic resources of the prairie land--the soil and the grass sod which protected it.""* (USFS, 1994) After the plains dust bowl and the Great Depression many homesteads were abandoned. The Thunder Basin National Grasslands was created by Congress in 1934.

In 1954, these lands were transferred from the Soil Conservation Service to the US Forest Service for management. There are currently 267 grazing allotments and 231 separate grazing permittees, accommodating 177,400 Animal Unit Months (AUM's) yearly[3]. (USFS 1990) The average size of a ranch operation (private and public lands combined) is 8,000 acres.

---

[3] The equivalent of 160,500 animal units per month in the Thunder Basin and 16,900 in the Laramie Peak region.

(USFS 1990) TBNG accommodates 24,000 head of cattle and 21,000 head of sheep, and 3,200 miles of road (USFS 1990). Currently every acre is leased for mining, presently including 450 oil and gas wells, 5 coal strip mines, numerous deposits of uranium, an operating uranium mine, and 33 abandoned bentonite mines (USFS 1990).

Industry in TBNG

Like a majority of the public lands in the Northern plains, TBNG is a jumble of public lands and private inholdings (See Figure 1 ; **Thunder Basin National Grasslands,** p. 10) that encompasses 1,799,918 acres through eight counties.[4] It boasts one of the largest single ranger districts in the country, the Douglas Ranger District in Douglas, Wyoming (USFS, 1990). Private inholdings in TBNG comprise 56% of the region. Currently the region is divided into three grazing associations: Spring Creek Association in northern Cook and Campbell counties; Inyan Kara Association in Weston and Niobrara counties, and the Thunder Basin Association in Converse, southern Campbell and Weston counties. Over 188,500 Animal Unit Monthly are permitted yearly in the TBNG.

Thunder Basin National Grasslands experiences many ecological, political and cultural situations that seem to typify the northern grasslands. At present, the management and land distribution in the TBNG is not adequate to support a healthy, naturally functioning grassland ecosystem.

---

[4] TBNG extends 92 miles east and west and 192 miles north and south. The total number of USFS acres is 1,799,918 within TBNG. Private acres total 1,114,348 acres. State lands total 133,346 acres.

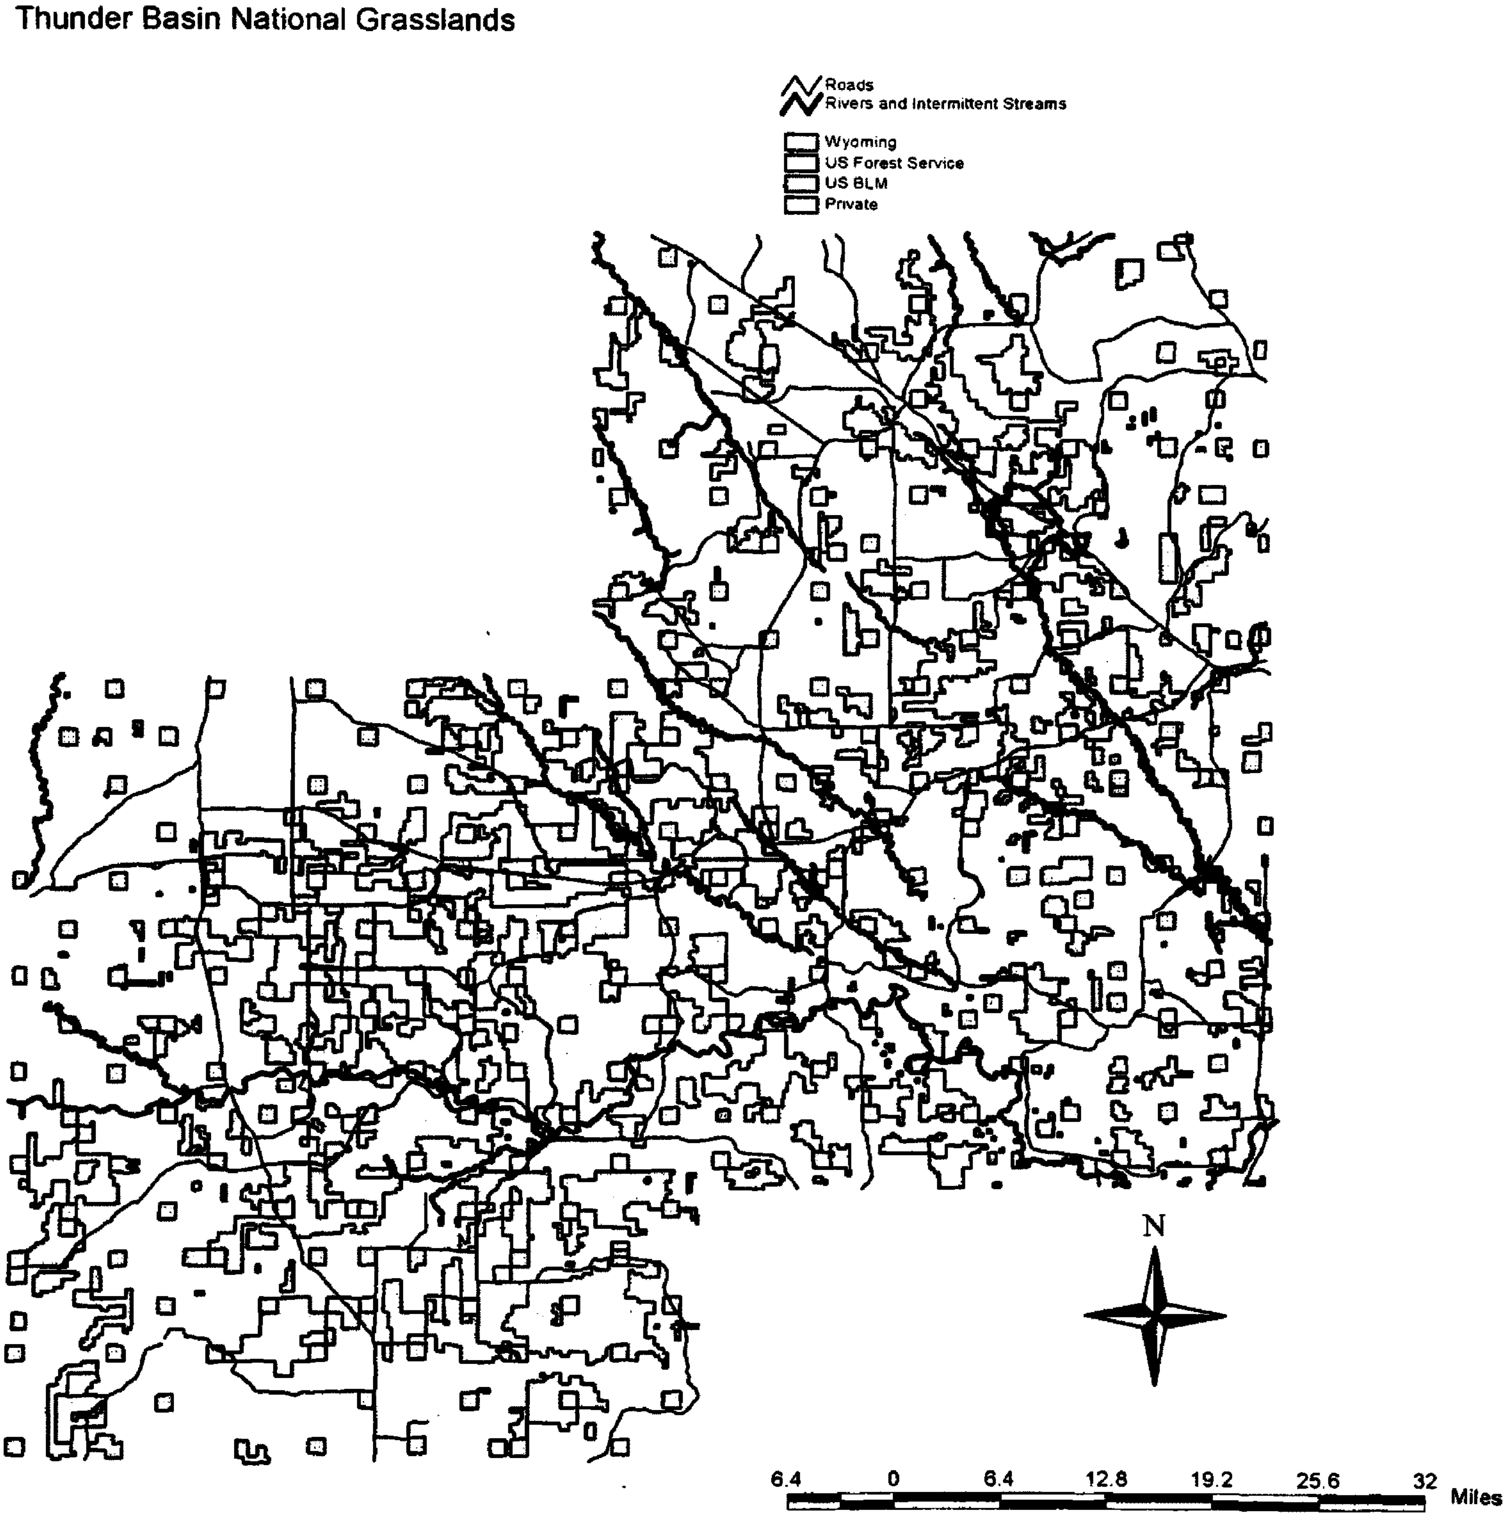

Figure 1. Thunder Basin National Grasslands ownership patterns.

Without restoration, this area would make a poor candidate for bison and ferret re-introduction [5]. Wildlife takes a back seat to livestock in management considerations.

Despite the proven historic inability for this region to sustain large ranching and farming efforts, ranching is the central use of TBNG and management focus. The area is managed almost completely for its commodity resources with little thought given to its ecological limits, attributes, or threatened or endangered species. Grazing allotments are not monitored and many allotments have no Allotment Management Plans (AMP'S).[6] In short, the grazing policies implemented by the USFS in TBNG are completely inconsistent with a healthy, diverse ecosystem or the productive capabilities of the area. USFS management's favoritism and short-sightedness prohibits TBNG from being both ecologically sound and recreation oriented.[7]

Replacing Biodiversity with Livestock

> *The proposed plan calls for grazing 245,000 AUM's per year to 250,000 in the next 10 years. Livestock management during the next 10 years would allow recovery of rangelands that are currently in less than satisfactory condition by redistributing grazing use to areas that are underutilized.*
> **(Medicine Bow Resource Management Plan for the Thunder Basin, 1985)**

Thunder Basin has thousands of cattle and sheep (250,000 Animal Unit Months) that graze habitat formerly occupied by the American bison.

---

[5] Thunder Basin National Grasslands has been recommended for a possible site for black-footed ferret re-introduction and bison re-introduction. (USFS, 1989)

[6] At present over 70 allotments at TBNG lack AMP'S. AMP's over ten years old total over 36.

[7] There are no campgrounds on the the grasslands, although there are four on Laramie Peak.

Native grazers, such as pronghorn, antelope, and deer[8] are still prevalent in TBNG and continue to graze along with cattle; but for the bison, millions of prairie dogs, black footed ferrets, wolves, grizzly bears, and natural grass communities, a hundred years of agriculture and mining in the TBNG have caused extinctions and declines in populations of many native species. (USFS, 1992) Presently, the following species in TBNG are identified as threatened, according to a 1992 USFS inventory:

Fish

Flathead Chub, (Hybopsis gracilis) found in Antelope Creek, the Cheyenne River, and the Little Powder River
Plains Topminnow, (Fundulus scaiadicus) , found in North and South Platte drainages, the Niobrara river and the headwaters of the Cheyenne River system.

Reptiles

Milk Snake, (Lampropeltis trianqulum) , found in prairie systems, broadleaf riverbottoms and under decaying wood.
Black Hills Red Bellied Snake, (Storeria occipitomeoculae pahasapae) , found in the Upton/Osage area.

Amphibians

Tiger Salamander , (Ambystoma tigrinum) found in intermittent streams and stock ponds.
Northern Leopard Frog , (Rana pipiens) found on pond and lake shores in cattails, sedges and tall grasses.

Mammals

Townsend Big Earred Bat, (Plecotus townsendii) found in Upton-Osage region.

---

[8] There are opposing studies on whether cattle compete with prairie antelope, deer and elk for forage. (Jacobs, 1991 and TBNG study USFS, 1990)

Fringed-tailed Myotis , (Myotis thysanodes pahasapensis) found in Weston, Cow Creek and Downs areas.
Swift Fox , (Vulpes velox) still found in upland habitats of TBNG.

Birds

American Bittern, (Botaurus lentiginosus) summer resident very rare in TBNG. Found in riparian areas
Western Yellow Billed Cuckoo, (Coccyzus americanus) found in riparian areas.
Greater Sandhill Crane, (Grus canadensis) found in wetlands.
Long-Billed Curlew , (Numenius americanus) found in sagebrush and grassland types.
Ferruginous Hawk , (Buteo regalis) found in grasslands--ground nesters.
White-faced Ibis , (Plegadis chihi) found in the wetlands on the grasslands.
Common Loon , (Gavia immer) found along river banks.
Merlin, (Falco columbarius) found in cottonwood river bottoms throughout the year.
Western Burrowing Owl , (Athene culumbarius) found in vacant prairie dog burrows on the grasslands.
Loggerhead Shrike , (Laniuius ludovicianus) found upland sagebrush and grasslands.
Fox Sparrow ,(Passerella iliaca) found in riparian shrublands.
Black Billed Woodpecker , (Picoides acrticus) found mainly in burned forests.
Mountain Plover , (Charadrius montanus) found on grasslands with level topography and short grasses; prairie dog towns.
Upland Sandpiper , (Bartramia longicauda) found on grasslands.
Baird's Sparrow , (Ammodramus bairdii) found nesting on ground in grasslands.
Black Tern , (Chlidonias niger) found in riparian regions.
Lewis Woodpecker (Melanerpes lewis) found on cottonwood bottoms and in ponderosa pine stands.
(USFS, 1992)

According to a 1991 USFS survey, pronghorn antelope populations total 54,307; mule deer populations total 26,900; white-tailed deer populations total 1,651; elk populations total 2,404; big-horned sheep total 212 and 12 moose (in the Laramie Peak region) (USFS, 1992). Prairie dog towns cover 13,000 acres, although a recent sylvatic plague outbreak has wiped out a significant number of rodents within Thunder Basin and exact prairie dog population numbers are unknown (USFS, 1995). Predators include black bear, bobcat, coyote, raccoon, skunk, mountain lion, ermine, badger, long-tailed weasel, red fox, and swift fox. No black-footed ferrets have been found in this region since the 1970's.[9]

TBNG presently provides habitat for over 228 bird species (60 neotropical species), including ferruginous hawks, peregrine falcons, burrowing owls, and mountain plovers as well as 62 mammals, 15 reptiles, 28 fish and 6 amphibian species (USFS 1990). Bald eagles and Golden Eagles nest in TBNG. The TBNG has a variety of habitats: old growth ponderosa pine stands, shrub and sagelands, scoria outcroppings, marshes, river bottoms, cottonwood stands, and shortgrass plains supporting 22 different plant communities inhabited by 250 species of vascular plants. The rivers in TBNG include the Little Powder, Little Missouri, Bell Fourche and the Cheyenne River (USFS, 1992).

Grazing and so-called grazing improvements have been a significant ecological and financial burden to the High Plains. Cattle management includes pest elimination programs (coyote and prairie dog management); fire-suppression, a practice that prevents vegetation communities from

---

[9] A population of black-footed ferrets was discovered in 1982 on a ranch in Shirley Basin, about 100 miles west of TBNG

reaping fire's healthy benefits; fencing and barbed wire; and roads (Ferguson and Ferguson, 1983).

"Pest" control, a component of the TBNG grazing pragram, has been responsible for reducing prairie dog range 98% (Clark, 1989). Between 1982 and 1992, Federal and State governments have been responsible for poisoning 1,193,203 acres of prairie dog habitat, and despite shrinking prairie dog populations, control programs continue at the TBNG full speed ahead (USFS, 1989). From 1989 to 1992, over $388,700 was spent on prairie dog control programs on state, private and federal lands in Wyoming (Forrest and Roemer, 1993). Indirect costs for grain and aluminum phosphate totaled over $50,000 (Forrest and Roemer, 1993). Most of the funds went to Campbell County, the Medicine Bow National Forest and TBNG (Forrest and Roemer, 1993).

Predator control for ranching operations has been responsible for the innumerable deaths of coyotes, mountain lions, bobcats, bald and golden eagles (Jacobs 1991). Control programs have also been responsible for wiping out the wolf, swift fox, black bear and grizzly from the plains region (Jacobs 1991). Animal Damage Control (ADC) uses aerial hunting, traps, snares and carbon monoxide poisoning on coyotes in TBNG (USDA, ADC, 1993).

Although the black-footed ferret is currently being re-introduced to areas in Montana and Wyoming, the ferrets have a low probability of attaining a viable population if not enough effort is made to protect the prairie dog (Forrest, 1993). Ferret populations declined originally due to lack of prey base (99% of their diet are prairie dogs) and diminishing habitat.[10] Without a healthy population of prairie dogs, 10-30 per hectare (O'Mielia, 1980), black-footed ferrets will not find a suitable prey base if re-introduced to TBNG.

Grazing and Vegetation

> *Native annuals have been greatly depleted and even extirpated by from many areas* [in the Plains] *by grazing. Over even greater areas, ranching's "desertifying" effects have eliminated perennial ground cover and created conditions favorable to annuals--exotic annuals.* (Jacobs, 1991)

The vegetation in the plains has also been altered due to cattle grazing. The rarest grasses on the grasslands are generally the most sought after by livestock (Jacobs, 1991). Undesirable species and exotics come in after the native species are eaten, causing shifts in vegetation patterns.[11] Bare soil, an effect of over-grazing, allows erosion, floods, and prevents proper moisture absorption by the soils. Riparian areas, rare and vital parts of the prairie, are damaged by cattle trampling stream banks and sensitive vegetation, such as cottonwoods and sedges. Reduction in streamside vegetation makes flash floods a real danger through erosion and the destablization of streambanks (Jacobs, 1991).

---

[11] Cheatgrass, an invader common in TBNG, followed cattle into the plains around the turn of the century. It is an inferior grass to native grass and causes injury to livestock by lodging in soft animal tissues. (Jacobs, 1991)

Mining

Extensive oil and gas field development has occurred on state and private land, as well as on federal... The character of the entire area is heavily influenced by oil and gas development, such as oil rigs, pumpjacks, storage, treater tanks, pipelines, power lines and oilfield roads and traffic.
(TBNG USFS overview, 1990)

The Forest Service has opened up 100% of the Thunder Basin National Grassland to oil and gas leasing, and ten new wells are developed annually. TBNG has 58 developed oil fields with 1,500 wells[12], and each field is accessed by its own road and pipeline system. The Forest Service reports that coal underlies a majority of the Thunder Basin region: "thousands of acres of coal deposits with a high to moderate potential for development" exist (USFS, 1990). At this point, five coal mines operate on 3,700 acres of public land. Annually, the mines produce 55,000,000 tons of coal. Presently, oil, gas and mineral revenues exceed $27 million in annual profit (USFS, 1990) .

There are two operating bentonite mines in the Thunder Basin. Since the price of bentonite is down, however, mining activity is low. Bentonite mining has gone through lucrative spurts and currently 33 abandoned bentonite mines are left awaiting reclamation funding (USFS, 1990). Only one uranium mine exists on TBNG, although there are many other abandoned uranium mines. Sand, gravel and building stone are currently mined on TBNG. Hard rock mining experienced a boom at the turn of the century on Laramie Peak, however today only one prospecting operation

---

[12] Only 400 wells on the Thunder Basin are producing wells.

exists. "Old claims" on Laramie Peak are under analysis for hazard mitigation and reclamation work (USFS, 1990).

There are no areas within TBNG that are off limits to mining. Riparian and wetland areas; steep slopes; unstable soils; raptor and grouse nesting sites are all subject to unmitigated mining disturbance (Keopsel, 1992). Road building, erosion of unreclaimed mining sites and excavation are documented causes of watershed siltation, water contamination, and destruction of habitat and vegetation patterns in riparian areas (Smith, 1995). Mining is a danger to water quality in TBNG (Keopsel, 1992).

Ownership Patterns

The TBNG is a mixture of state, BLM, USFS and private lands (see Figure 1; **Thunder Basin National Grasslands**, p. 10). Homesteading saw the rise of sod busting on the plains, but when the wheat price peaked and plummeted in the early 1930's, two and a half million people abandoned their dryland farms. The acreage of these homesteads reverted back to federal land with the creation of the Bankhead-Jones Farm Tenant Act. This accounts for the checkerboard pattern, or blocks of federal land interspersed with private inholdings throughout the plains. On TBNG, only 44% of the lands are public, and the remaining 56% are private inholdings (USFS, 1990).

Chapter 2

Conservation Biology and Ecosystem Recovery

Conservation biology is "the application of science to conservation problems, addressing the biology of species, communities, and ecosystems that are disturbed, either directly or indirectly, by human activities and other agents" (Cooperrider, 1994). As it stands, USFS management in TBNG overwhelmingly favors resource development to the exclusion of conservation biology principles and biodiversity.[13] Management direction at the Douglas Ranger District lacks conservation aims essential to grassland recovery. In order to address the conservation problems in TBNG and restore the natural systems of the prairie ecosystem, conservation biology needs to enter management, practice and philosophy. The following excerpts outline the difference between the conservation planning criteria in the Medicine Bow Grasslands Resource Management Plan (RMP) and Noss and Cooperrider's (1994) criteria for conservation planning in *Saving Nature's Legacy ; Protecting and Restoring Biodiversity* .

---

[13] According to the "USFS Rules of Management for Thunder Basin National Grasslands Grazing Associations", TBNG objectives call for "progressive principles of land conservation and multiple use, the development of grassland agriculture and sustained-yield management of the range resources within the Association. " USFS goals call to " demonstrate livestock grazing associated with other uses in a way, that when practiced on these lands, will provide the greatest return from the investment in multiple use management and the best use of all lands in the area. " There is no use of the term biodiversity or ecosystem in the entire document.

RMP (USFS, 1985)

1) Promote and develop grassland agriculture and sustained yield management of the fish and wildlife, timber, water, and recreation resources in the area.
2) Demonstrate sound and practical land uses for the area.
3) To the extent feasible, integrate federally owned land with the associated private lands into natural management units which favorably influence development of sound land conservation and and utilization practices suitable for use in the area.
4) Provide a biological benchmark in man's quest to live harmoniously with extremes of climate, land and economic fluctuations.
5) Serve as an applied range management laboratory testing the latest techniques in grassland agriculture and determining sound land management and sustained production.
6) Provide for rural development and economic and social stability of local communities.

SNL (Noss and Copperrider, 1994)

1)Maintain viable populations of all native species
2) Represent within protected areas, all native ecosystem types across their natural range of variation.
3) Maintain evolutionary and ecological processes (i.e., disturbance, regimes, hydrological processes)
4) Manage over periods of time long enough to maintain the evolutionary potential of species and ecosystems
5) Accommodate human use and occupancy within the above mentioned constrains.

Comparing the above priorities, it is easy to see that the USFS is more committed to resource extraction in the TBNG than to the ecological integrity of the ecosystem. The conservation biologists frame their goals within a holistic structure, allowing human use only if it meets the goals of the above mentioned criteria (#5, SNL) for a healthy environment. The RMP looks at TBNG as an "agricultural laboratory"(#5, RMP), or a "benchmark" set up to accommodate human use despite the ecology, topography and climate (#4,6, RMP) of the TBNG. Before management specifics are addressed within the Thunder Basin region, a shift in management philosophy is essential. If the area is to accommodate native species such as the black-footed ferret, swift fox or bison, TBNG needs to be perceived as a prairie ecosystem (Forrest, 1994) rather than a "laboratory for the latest techniques in grassland agriculture."

Although the Medicine Bow National Forest and Thunder Basin Resource Management Plan addresses "wildlife", the management goals focus on game species and not the many other members of the region's biotic community. Resource managers manage game species and livestock, but fail to address non-game species, many of which aren't even studied. (Alverson et. al, 1994) This approach leaves out key ecosystem components and prevents a holistic approach to resource management and ecosystem integrity.

Conservation Biology and the Noss Model

Wilderness recovery , I firmly believe, is the most important task of our generation

(Reed Noss, 1992)

Biodiversity

Reed Noss, a conservation biologist and the Science Editor for *Wild Earth,* explains that implementation of conservation principles requires large pieces of contiguous roadless habitat to support genetic variability, to withstand environmental disruptions (disease, fire, weather patterns) and to promote evolutionary potential with a long-term vision (Noss, 1992). Land pieces need to be connected by a network of corridors to form interconnected core reserves that allow for genetic cross-over. With this model in mind, large blocks of habitat first need to be identified within the TBNG, and then acquired, connected and protected.

To cobble together an ecosystem protection plan, TBNG must first consolidate federal lands and if need be, private lands. Acquisition of private lands that connect public pieces to create a contiguous reserve,[14] should be an essential goal in the TBNG Resource Management Plan in order to accommodate large predators, bison, and prairie diversity. At present, the TBNG Land Swap Program is available to local landowners who want to buy or trade for public lands. The program is for ranching and the concept of seeking and acquiring lands of ecological importance is not a component of the program. If contiguous habitat is to be achieved, a strategy could be to shift the Land Swap Program focus from "ranch real estate" to "conservation real estate."

Noss suggests the following guidelines for management goals subsequent to establishment to core habitat:

* Maintain minimum viable populations well distributed across native ranges
* Maintain large blocks of habitat for target species
* Habitat blocks should be close together
* Habitat should be contiguous
* Corridors should connect habitat blocks
* Blocks of habitat should be roadless[15]

Wildlife includes all species living in the prairie biotic community, even species perceived as pests. A focus on the minimum viable

---

[14] Contiguous habitat is essential in preventing isolated populations and weak genetic pools. (Noss, 1992)

[15] According to Steve Forrest, Ph.D., roadless area for the prairie species community may not be as important as it is to the forest species community.

population[16] numbers of prairie dogs should be every bit as important in USFS management goals for the TBNG as pronghorn, deer and elk numbers. Prairie dog communities provide habitat for 164 species (Carlson, 1995) but due to fragmented habitat, disease and an active prairie dog extermination program, prairie dogs are declining at a dangerous rate taking dependent species with them.[17] Carnivores should also be a primary target species for protection and the health of mountain lions, bobcats, and badgers needs to be part of USFS management goals. By assuring minimum viable populations of all species on TBNG, an entire community is accounted for.

Monitoring

One glaring problem in the management of TBNG is the complete lack of routine species monitoring. Although vague references are made in the RMP, transect studies on vegetation on TBNG are intermittent, incomplete, and outdated[18]. Entire regions are overlooked and unknown. A common form of monitoring in TBNG allotment files is the "ocular exam", a drive-by glance of a fence or stock pond. Remarks on inventory sheets are typically, "looks good! not overstocked, etc........" This is not a measurable, accurate form of monitoring. To understand the region and the biota, gap analysis[19] is necessary. Geographic Information System (GIS) integration of a full species

---

[16] A viable population is a population with a high probibilty of survival, which according to Noss is 95% or 99%, probability of population persistence for 100 to 1,000 years.

[17] Concerns about population viability should be directed toward species at most risk of extinction in a region. (Noss, 1992)

[18] Many allotments have transect studies dating back to the 1960's.

[19] Gap analysis is a measurement of different community types and species representation within an ecosystem (Noss, 1992). Currently the US Fish and Wildlife is conducting gap on a state wide basis.

inventory, and ground-truthing is also desperately needed. Monitoring needs to be "consistent and scientific."

The following monitoring suggestions are taken from the "Scientific Round Table on Biological Diversity," (Crow et al 1993). The remarks that follow the italicized suggestions may be ecologically beneficial to a new management plan for TBNG:

1) Inventory and monitoring efforts should be expanded and systematized to place them on the best scientific footing to ensure a continual yield of high-quality and timely information.

TBNG- Monitor TBNG on a rotation basis so that each 50 acre by 50 acre section gets assessed every five years.

2)*Research and monitoring should employ the best contemporary science knowledge and methodology. To ensure this process, programs should undergo under peer review.*

TBNG- **Visual or ocular examination, common in allotment files, is not a scientific method of monitoring.** USFS should consult with range biologists and conservation scientists specializing in prairie ecology and begin to use GIS and gap analysis, followed by ground-truthing, to review the prairie ecosystem.

3) Research and monitoring should emphasize those elements of diversity thought to be vulnerable to extirpation, sensitive to man-made disturbances, or keystone species with cascading effects on other elements of diversity.

TBNG- **Shift the research focus from forage for livestock towards the needs of native species within the grasslands ecosystem! This will serve to address the dwindling biodiversity on the TBNG. Studies should focus on**

mountain lion and swift fox populations; riparian health; ferruginous hawks; prairie dogs and plague; and finding native grasses and natural vegetative grasses among degraded prairie.

4) Inventory and monitoring should be extended to include other important but obscure groups of organisms.

TBNG- So little is known of invertebrates in the grasslands. Studies are in order to understand the entire biotic complex.

5) Whenever possible use demographic structure or other early warning signs to assess changed ecological conditions rather than population numbers.

TBNG- Models on weather patterns, disease and other factors effecting population fluctuations should be an ongoing component of TBNG research.

6) Monitoring should occur at a hierarchy of geographic scales.

TBNG- Begin to seek information on corridors, buffer zones as well as on additional area that effects the TBNG.

7) Inventory and monitoring efforts should include entire guilds or communities in cases where such sampling is sufficient.

TBNG- As gap analysis maps are produced, the monitoring of community and species representation at TBNG should measure growth in diversity and biomass over the years as grazing and mining activities are discontinued and the ecosystem regenerates.

8) The results of research projects and monitoring efforts should be closely integrated with management!

TBNG- The predominant consideration in TBNG management is presently livestock, livestock forage and game populations. Monitoring and studies has to shape the understanding of an entire ecosystem and all species. The "see-no-evil, hear-no-evil, speak-no-evil" policy in habitat management has to stop for this region to revive and survive.

Chapter 3

TBNG Management Reform

Federal Designations

There are limited options for a federal protective designation of TBNG. TBNG is a roaded, degraded ecosystem and does not have a 5,000 acre block of unroaded area and therefore does not qualify for a Federal Wilderness designation. Restoration and protection of this area requires creative legal and policy methods if it is to become federally protected. Possible existing designations include:

National Recreation Area (NRA)
National Park Act (16 USC § 460 et. seq.)

An area that can provide special management to its resources. The Glen Canyon NRA has cow-free zones, numerous hiking and boating access points and low-intensity management. The focus of an NRA is on recreation rather than resource extraction.

Research Natural Area (RNA)
National Forest Service Regulations (36 CFR § 251.23)

An area that is protected to preserve rare habitats and associated species. The RNA designation states "protect habitat for its own sake that is considered rare and unique." Since the prairie dog communities in TBNG are becoming increasingly rare and have a great many associated species, this may be an appropriate designation to seek. The Konza Prairie Preserve in southern Kansas is an example of a Research Natural Area.

National Monument
National Monument Act (16 USC § 1 et. seq)

With President Clinton considering the Arctic National Wildlife Refuge for National Monument status, this may not be far-fetched. A National Monument status could protect TBNG without going through Congress. This designation could prevent all grazing, mining and roading; restore the region; and encourage tourism.

National Park
National Park Act, (16 USC § 1 et. seq.)

A National Park designation would be the most favorable as it would provide TBNG with the most protection, allowing relief to an injured ecosystem. Also a National Park is education and resource oriented and could expose the public to the High Plains ecosystem. Local economies could benefit from a Plains Park with bison, native grasses, interpretive centers, and opportunities for recreation.

Legal Strategies

Legal action may be the best way to produce concrete management shifts during the short term, although in the long term a federal designation beyond "National Grassland" is preferable. USFS and BLM grazing allotments are being legally challenged all over the west on the grounds that grazing imposes a threat to riparian areas and sensitive or critical habitat, threatened and endangered species and water quality. Legal strategy may work well to fight the site specific issues of TBNG current management.

TBNG's ecological integrity has been put on the back burner by the Douglas County Ranger District and current grazing policies show a lack compliance with federal grazing laws and rules. Many allotments have no Allotment Management Plans. Most allotments have no routine monitoring program. There are even some allotments that have never been inventoried or cataloged for grass species or wildlife. The USFS is not doing their job by not monitoring the lands at TBNG. Prairie species stand defenseless due to biased alliances between livestock and federal management .[20]

In order to legalize protection for the prairie, appeals or a suit might be in order. USFS management in TBNG may be out of compliance with the following laws:

* *Taylor Grazing Act of 1934* (43 U.S.C. § 315-O-1; TGA) states that the governing federal agencies must " stop injury to public grazing lands by preventing overgrazing and soil deterioration." This act was developed following the decimation of "commons" rangeland in the early 1900's. *TGA* sets up an allotment and lease system, "to preserve the land and its resources from destruction or unnecessary injury." (43 U.S.C. 315a)

TBNG- Thunder Basin allotments have no routine monitoring program (see p. 23), and therefore the condition of the range in many areas is undetermined.

---

[20] **Excerpt from 1991 letter from Douglas County Distric Ranger to Grazing Association Members in the TBNG regarding increased criticism of grazing on public lands-- "These are a few things that need to be done to ensure livestock grazing has a long future on public lands. Help us help you. If either of us are fail [to pass public scrutiny] , both of us lose."**

* *Multiple Use and Sustained Yield Act of 1960* (16 U.S.C.A. §§ 528 to 531; MUSYA) states that agencies managing public lands need to manage for multiple use. *MUSYA* defines multiple use as "the management of various sustainable resources of the national forests so that they are utilized in the combination that will best meet the needs of the American people making the most judicious use of the land...without permanent impairment of the productivity of the land, with consideration being given to the relative values of various resources, and not necessarily the combination of uses that will give the greatest dollar return or the greatest unit output." (MUSYA 15 CFR 531 (a).

If the best use of a piece of public land does not include grazing, *MUSYA* requires that the agency adopt a **no grazing policy**. (see *Sinapu v. Jerry Schmidt,* Sept. 2, 1994, pg 59; see Appendix C)

TBNG-- In TBNG grazing in riparian areas, hillsides, near uranium mines, near historic landmarks and in sensitive habitat may not be the best use of the land.

MUSYA* also demands that action "significantly affecting the quality of the human environment" needs to be researched through the preparation of an Environmental Impact Statement (EIS). EIS documentation and analysis notifies the public and Congress to the negative environmental impacts, alternatives of the action, cumulative effects and irreversible effects (43 U.S.C.A. § 4332). Major actions on public lands include **grazing programs (DEQ, Environmental Quality 182).

Administrative Law Judge John Rampton decided in *National Wildlife Federation v. BLM (UT-06-91-1994)* that an EIS for an entire resource area (in this case, the San Juan Resource area) may be insufficient to address every allotment within that area. An EIS for an individual grazing allotment with site specific considerations (e.g., riparian areas) was required for Comb Wash due to the degradation wrought by livestock grazing and the sensitive nature of the canyons (UT-06-91-01 Department of the Interior, Office of Interior and Appeals Div, Dec. 20, 1993)

TBNG- If "substantial questions have been raised whether a project may have significant effect upon the human environment, an EIS must be prepared" (*Sierra Club v., USFS, 843 F.2d 1190, 1193 (9th Cir. 1988)*). No grazing related EIS has ever been prepared for an allotment in TBNG. This creates an opportunity to find an area in TBNG used by hunters or fisherman that has been degraded by livestock-- "significant effect on the human environment."

**Endangered Species Act of 1973* (16 U.S.C.A. 1531 to1544; ESA) mandates that "each federal agency shall, in consultation with and with the assistance of the Secretary, insure that any action authorized, funded or carried out by such agency is not likely to jeopardize the continued existence of any endangered plant and wildlife species listed as endangered or threatened species or result in the destruction or adverse modification of habitat of such species as listed by the Secretary" 16 § 1536, 7(a)(1).

Pacific Rivers Council v. Thomas, 30 F.3d 1050 (9th Cir. 1994) found that the USFS grazing program was subject to the "may affect" standards of the ESA in cattle's adverse effects on endangered salmon species.

ESA also states that endangered species must be **managed with the objective of becoming delisted.** It is up to the agency to see how grazing effects endangered populations. Federal grazing practices may be inconsistent with ESA delisting objectives on an allotment with populations of endangered species.

TBNG- TBNG may be a reintroduction site for the black-footed ferret (USFS, 1990). Since black tailed prairie dogs are the primary food source to the black-footed ferret, it may violate ESA to manage with a Prairie Dog Management program, currently in place to poison prairie dogs on grazing allotments.

* *Federal Land Policy and Management Act of 1976* (43 U.S.C. §§ 1701-1784; FLPMA) states that "public lands be managed in a manner that will protect the quality of scientific, scenic, historical, ecological, environmental, air and atmospheric, water resource, and archeological value; that is, where appropriate, will preserve and protect certain public lands in their natural condition; that will provide food and habitat for fish and wildlife and domestic animals; and that will provide for outdoor recreation and human occupancy and use."

FLPMA also states that "permits can be revoked or suspended if the permittee violates or does not comply with Federal laws or regulations or State laws relating to the protection of air, water, soil and vegetation, fish and wildlife and other environmental values when exercising the grazing use authorized by the grazing permit." (36 CFR § 231.6 1977)

FLPMA provides guidelines for development and management of **Allotment Management Plans (AMP)**, the document that accompanies each federal grazing allotment. AMP's outline site specific information such as Animal Unit Months (AUM) , range improvements, wildlife habitat and permittee information. The AMP is a "**document prepared in consultation with the lessors or permittees involved, which applies to livestock operations on Forest Service or Bureau of Land Management lands, and which (*inter alia)* prescribes the manner in, and extent to which livestock operations will be conducted to include multiple-use, sustained yield, economic and other objectives as determined for the lands by the (*agency*)**" (43 U.S.C.A. § 1702 (k)). AMPs define range improvements that managing agencies plan to administer during the 10 year life of the plan; improvements that must prove consistent with the provisions of *FLPMA* 43 U.S.C.§1702 (k) as well as with the existing land management plan. In the case of grazing allotments that are inconsistent with a governing land plan, an AMP must include an expected date to come into compliance.

Permits on allotments are issued yearly explaining the type of livestock to be grazed on the allotment , the AUM and rotation schedules, seasonal pasture use and closures (43 C.R.F § 4130.6-1(a)). If the conditions of an annual permit is violated, the permit agreement can be canceled (43 C.R.F. § 4130.6-1(b)). AMP development or AMP changes are subject to NEPA and can be appealed under *FLPMA* (36 C.F.R.§ 251 or 36 C.F.R. § 217).

Under FLPMA, USFS and the BLM must determine if the practice of livestock grazing on an allotment is "a reasoned and informed decision as to whether grazing is in the public interest." (see *Sinapu v. USFS*, Appendix C)

TBNG-- There are over 100 allotments in TBNG that have never had an AMP completed. It could be possible to get an injuction on grazing until the AMPs are completed. (This could take a long time). As yet, the National Wildlife Federation (see *NWF v. USFS,* Appendix C) threatened get an injunction , but backed down due to local pressure from ranchers.

**National Forest Management Act of 1976* (16 U.S.C. § 200; NFMA) states that grazing permits issued must be consistent with the goals of corresponding land plans.

NFMA requires "Resource plans and permits, contracts, and other instruments for the use and the occupancy of National Forest system lands shall be consistent with the land management plans. Those resource plans and permits, contracts, and other such instruments currently in existence shall be revised as soon as practical to be made consistent with such plans." (16 U.S.C. §1604 (i)).

In implementing land plan regulations in AMPs, the Forest Service must include "a tabular display showing, in priority order, AMP revision, territory plans, and other grazing/browsing documents, and conform them to the management direction of the Forest Plan" (FSM 2200-Range Management, FSM 2213.1-Revision Schedules). In implementing a range analysis schedule, priority needs to be given to lands with riparian, soil, vegetation and water damage (FSM 2213.1 (1)).

TBNG- TBNG is so under supervised and researched, that range analysis has no routine or schedule. Transect monitoring is arbitrary and "ocular examines" are generally used for range assessment. This type of examination is arguably unscientific. Range damage is undetermined and unassessed and TBNG is clearly in violation of NFMA. Perhaps a grazing injunction is possible until a monitoring system is established. It could be that a court would freeze AUM levels until reliable monitoring occured.

Other Strategies

Legal routes may be costly, timely, and subject to congressional changes in the law. It is a strategy also often viewed as combative by community residents and allotment lessors. Whether legal victories bring grazing reform by the reduction of AUM's or complete livestock abolition, a community with a tradition in ranching will need assistance in acclimating to a new economy.

To accompany law suits, community outreach, town meetings, and bison ranching feasibility discussions may assist in easing High Plains residents toward an ecological reserve. In light of the controversies involved with livestock abolition on public land, attempts at community outreach may be better handled by groups not directly involved with legal action.

Chapter 4

Piecing Together an Ecosystem

Enforcing the Principles of Conservation Biology

What now remains compared with what existed then is like the skeleton of a sick man, all the fat and soft earth having wasted away, only the bare frame of the land being left.

(Erlich and Erlich, 1982)

Jumbled ownership patterns and intermittent distribution of wildlife populations leave TBNG fragmented in its present state. Currently TBNG can't support large bison herds or minimum viable populations of all native grasslands species (Forrest, 1994). However, there are opportunities for creating contiguous blocks with the goal of restoring this fractured ecosystem. A block of federal land in the Spring Creek Grazing Association, the center of TBNG, may be an area suitable for a reserve. This may be done through a land swap of BLM/USFS land for a small amount of private land.[21]

Within core habitat, management must allow nature to re-establish itself. Natural processes include nutrient cycling and flow of energy, disturbance regimes and recovery processes (succession), droughts and heavy rains, weathering and erosion, decomposition, herbivory, migration, predation, pollination, seed dispersal, parasitism, disease, mutation, gene

---

[21] TBNG has a land swap program that attempts to consolidate federal land, however the program does not seek to consolidate federal lands that are ecologically sensitive or strategic in the purpose of creating core habitat.

Thunder Basin National Grasslands Proposed Core Reserve

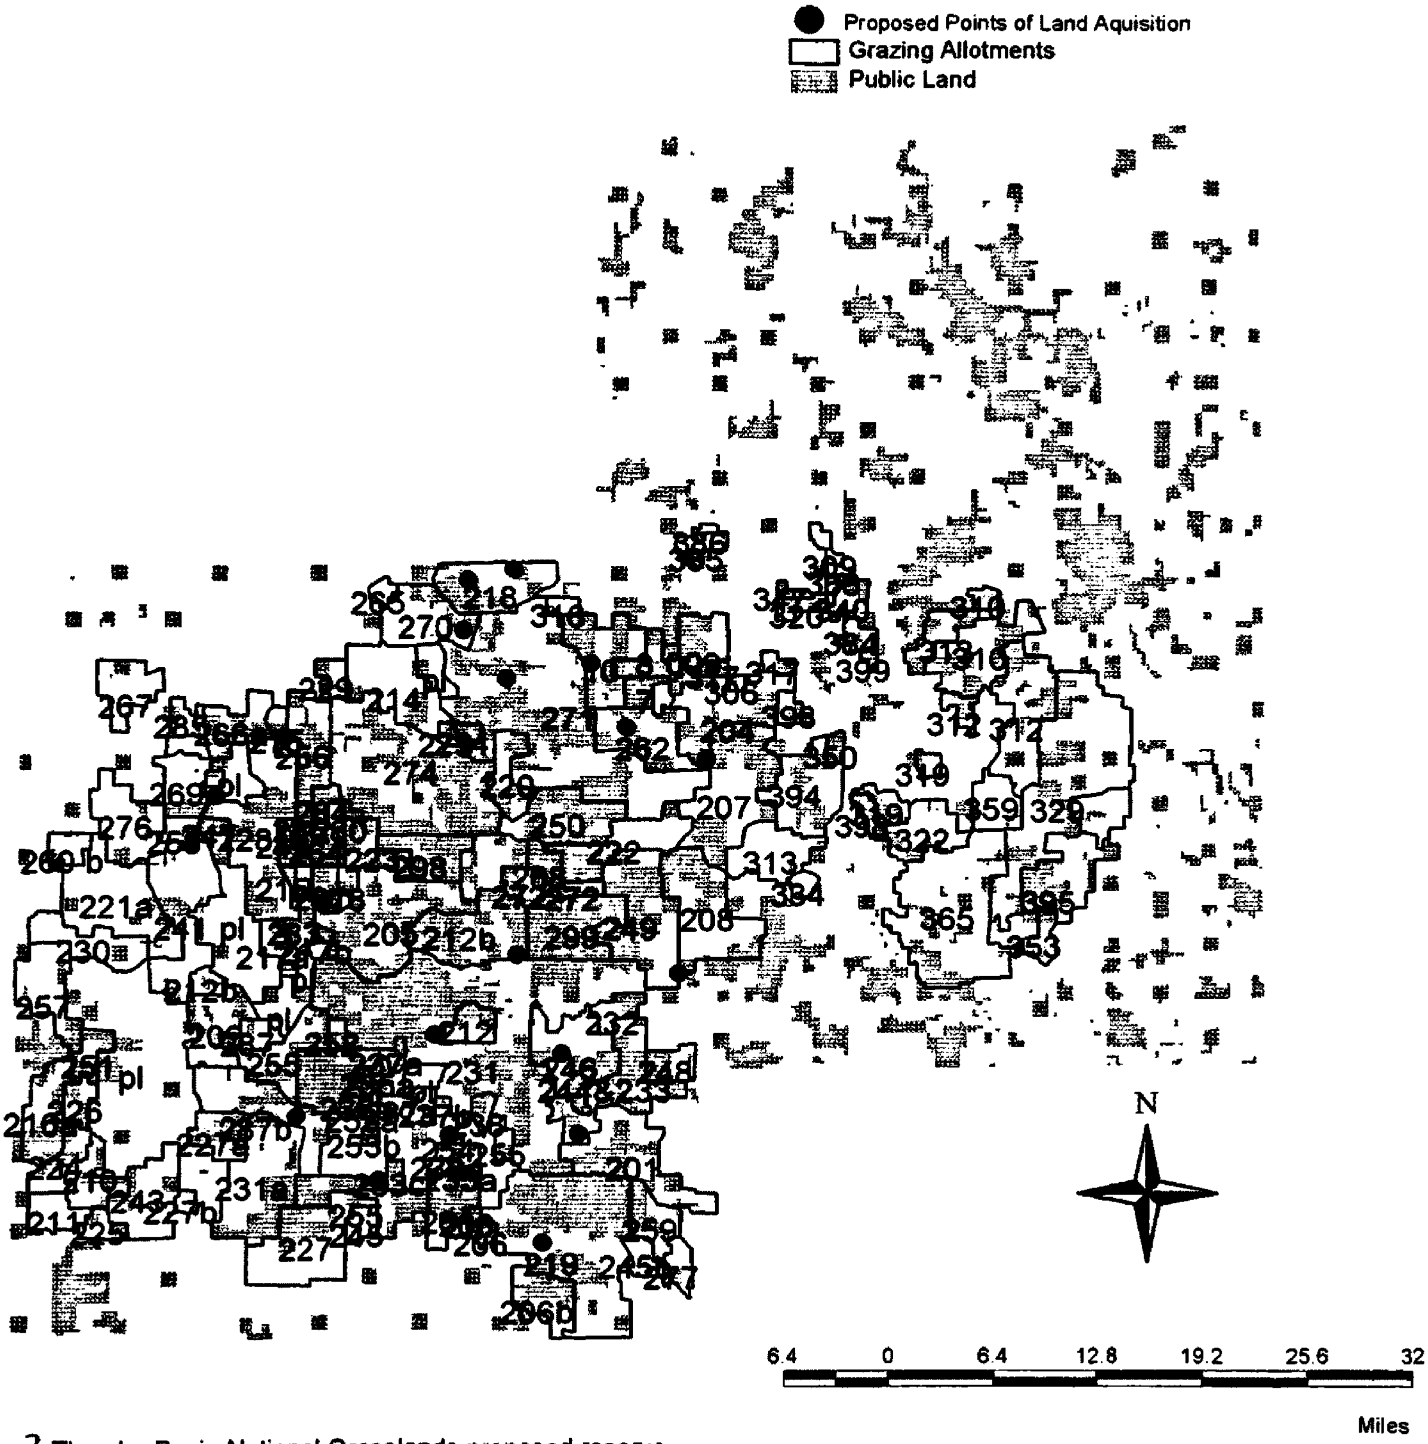

Figure 2.Thunder Basin National Grasslands proposed reserve, overlaid with grazing allotments with corresponding USFS allotment numbers.

flow, must also be restored and allowed to continue if the prairie ecosystem is to survive.

The following allotments fit together to form a core area of contiguous federal lands (see Figure 2; **Proposed Core Ecological Reserve**, pg. 36)

Allotments identified Core Habitat
(Douglas Ranger District)

206 B, Downs Allotment
vitals - This allotment has a total of 7643 acres, 3646 acres are USFS; 1044 AUM's in cattle. There are no riparian acres.
management aspects - The Allotment Management Plan (AMP) was done in 1987.

246, Rohleutner Allotment
vitals - This allotment has a total of 13196 acres, 5620 acres are USFS; 1723 AUM's in sheep and cattle. There are 10 riparian acres.
management aspects - The AMP was done in 1982 and is currently out of date: a violation of FLPMA and NFMA. Riparian analysis is needed and an EIS may be required.

201, Alexander -Allotment
vitals - This allotment has a total of 15999 acres, 5237 acres are USFS; 617 AUM's in sheep and cattle. There are no riparian acres.
management aspects - The AMP was done in 1981 and is currently out of date: a violation of FLPMA and NFMA.

010- Kara Community Allotment
vitals - This allotment has a total of 10830 acres, 6796 acres are USFS; 1710 AUM's in cattle. There are 551 riparian acres.
management aspects - The AMP was done in 1985 and is due for renewal in 1995. Riparian analysis is needed and an EIS may be required.

254, Wild Bill-Allotment
vitals - This allotment has a total of 800 acres, 160 acres are USFS; 28 AUM's in cattle. There are no riparian acres.
management aspects - The AMP was done in 1991.

287 Calamity Gulch Allotment
vitals - This allotment has a total of 17202 acres, 3369 acres are USFS; 567 AUM's in sheep and cattle. There are no riparian acres.
management aspects - There is no AMP; a violation of NFMA and FLPMA.

270 Ostlund Allotment-
vitals - This allotment has a total of 15318 acres, 2430 acres are USFS; 576 AUM's in cattle. There are 62 riparian acres.
management aspects - The AMP was done in 1984 and is currently out of date: a violation of FLPMA. Riparian analysis is needed and an EIS may be required.

266, Edwards Allotment
vitals - This allotment has a total of 6787 acres, 4440 acres are USFS; 1044 AUM's in sheep and horses. There are no riparian acres.
management aspects - The AMP was done in 1984 and is currently out of date: a violation of FLPMA.

269, Underwood Allotment,
vitals- This allotment has a total of 4418 acres, 1063 acres are USFS; 444 AUM's in sheep. There are no riparian acres.
management aspects- There is no AMP; a violation of NFMA and FLPMA.

258, , Taylor Allotment
vitals- This allotment has a total of 2511 acres, 1180 are USFS ; 273 AUM's of sheep. There are no riparian acres.
management aspects - The AMP was done in 1981 and is currently out of date; a violation of FLPMA and NFMA.

247, Sadler Allotment
vitals -There are a total of 3259 acres, 1760 are USFS; 461 AUM's of cattle and horses. There are no riparian acres.
management aspects - The AMP was completed in 1981 and is currently out of date: a violation of FLPMA and NFMA.

228, Mattheson Allotment
vitals - There are 19408 total acres, 4256 are USFS; 833 AUM's of sheep and horses. There are 21 riparian acres within the allotment
management aspects - There is no AMP; a violation of NFMA and FLPMA. Riparian analysis is needed and an EIS may be required.

275, Upper Basin Allotment
vitals - There are 2708 total acres, 775 are USFS; 177 AUM's of sheep. There are no riparian acres.
management aspects - The AMP was done in 1989.

215, Blow Out Allotment
vitals- There are a total of 985 acres, 640 are USFS; 191 AUM's of cattle. There are no riparian acres .
management aspects - The AMP was done in 1993.

217, Kane Allotment
vitals- There are a total of 4725 acres, 2098 are USFS; 456 AUM's of sheep. There are 51 riparian acres.
management aspects - There is no AMP; a violation of NFMA and FLPMA. Riparian analysis is needed and an EIS may be required.

212, Irwin Allotment
vitals- There are a total of 18287 acres, 11512 are USFS; 2683 AUM's of cattle. There are no riparian acres.
management aspects- There is no AMP; a violation of NFMA and FLPMA.

223, Mackey Allotment
vitals- There are a total of 5760 acres, 4550 are USFS; 149 AUM's of cattle. There are no riparian acres.
management aspects - There is a 1983 AMP that is no longer current; a violation of NFMA and FLPMA.

220, Small Allotment
vitals- There are a total of 6081 acres, 3065 are USFS; 605 AUM's of cattle. There are no riparian acres.
management aspects - There is an 1986 AMP which is up for renewal in 1996.

219, Ketelson Allotment
vitals- There are a total of 42019 acres, 19898 are USFS; 4560 AUM's of cattle. There are 245 riparian acres.
management aspects - There is a 1987 AMP. Riparian analysis is needed and an EIS may be required.

222, Lynch Allotment
vitals- There are a total of 18682 acres, 5135 are USFS; 1642 AUM's of cattle and horses. There are no riparian acres.
management aspects- There is a 1989 AMP.

264, Wilkinson Allotment
vitals- There are a total of 4043 acres, 2448 are USFS; 517 AUM's of cattle and sheep. There are no riparian acres.
management aspects- There is no AMP; a violation of NFMA and FLPMA.

286, Briggs Draw Allotment
vitals- There are a total of 1826 acres, 623 are USFS; 84 AUM's of cattle. There are no riparian acres.
management aspects- There is a no AMP; a violation of NFMA and FLPMA.

282, North Turner Allotment
vitals- There are a total of 1105 acres, 1105 are USFS; 172 AUM's of cattle. There are 31 riparian acres.
management aspects- There is no AMP; a violation of NFMA and FLPMA. Riparian analysis is needed and may need EIS.

274, Little Thunder Allotment
vitals- There are a total of 9327 acres, 5074 are USFS; 1480 AUM's of sheep. There are 65 riparian acres.
management aspects- There is a 1985 AMP which is out of date; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

288, Red Springs Allotment
vitals- There are a total of 7517 acres, 1845 are USFS; 176 AUM's of cattle and sheep. There are no riparian acres.
management aspects- There is a no AMP; a violation of FLPMA and NFMA.

255, Stoddard Allotment
vitals- There are a total of 17666 acres, 9990 are USFS; 2695 AUM's of sheep and horses. There are no riparian acres.
management aspects- There is an 1983 Allotment Management Plan (AMP), currently out of date; a violation of FLPMA and NFMA.

253, Steinle Allotment
vitals- There are a total of 2800 acres, 1600 are USFS; 415 AUM's of cattle . There are 25 riparian acres.
management aspects- There is a no AMP; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

259, Thomson Allotment
vitals- There are a total of 6600 acres, 3316 are USFS; 632 AUM's of cattle. There are no riparian acres.
management aspects- There is an 1981 AMP that stands five years out of date; a violation of FLPMA and NFMA.

249, Frog Creek Allotment
vitals- There are a total of 15573 acres, 9005 are USFS; 2590 AUM's of cattle and horses. There are 342 riparian acres.
management aspects- There is an 1985 AMP out of date at the end of 1995. The riparian acreage may require an an EIS.

283, Isenberger Allotment
vitals- There are a total of 2367 acres, 1089 are USFS; 270 AUM's of sheep. There are no riparian acres.
management aspects- There is an no AMP; a violation of FLPMA and NFMA.

262, Gordon allotment
vitals- There are a total of 8611 acres, 5454 are USFS; 2000 AUM's of cattle. There are 117 riparian acres.
management aspects- There is no AMP; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

268, North Rochelle Hills Allotment
vitals- There are a total of 3030 acres, 3030 are USFS; 374 AUM's of cattle. There are no riparian acres.
management aspects- There is a 1987 AMP.

235, Pellatz Allotment
vitals- There are a total of 1680 acres, 1200 are USFS; 327 AUM's of cattle. There are 103 riparian acres.
management aspects- There is an 1976 AMP, twenty years out of date; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

240, School Creek Allotment
vitals- There are a total of 21779 acres, 14780 are USFS; 632 AUM's of cattle. There are 213 riparian acres.
management aspects- There is an 1985 AMP, now out of date; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

231, Fiddleback Allotment
vitals- There are a total of 84102 acres, 41208 are USFS; 7788 AUM's of cattle and sheep. There are 249 riparian acres.
management aspects- There is no AMP; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

237, Betty Don Allotment
vitals- There are a total of 3071 acres, 1240 are USFS; 310 AUM's of cattle and sheep. There are 37 riparian acres.
management aspects- There is an no AMP; a violation of FLPMA and NFMA. Riparian analysis is needed and may need an EIS.

232, Dull Center Allotment
vitals- There are a total of 1947 acres, 1320 are USFS; 219 AUM's of cattle and sheep. There are no riparian acres.
management aspects- There is an 1983 AMP which is out of date; a violation of FLPMA and NFMA.

244, Tena Creek Allotment
vitals- There are a total of 7624 acres, 2620 are USFS; 767 AUM's of cattle . There are no riparian acres.
management aspects- There is an no AMP; a violation of FLPMA and NFMA.

299, Rosencrantz Allotment
vitals- There are a total of 12305 acres, 12305 are USFS; 2873 AUM's of cattle.There are 395 riparian acres.
management aspects- There is an 1986 AMP, which is out of date next year. Riparian analysis is needed and may need an EIS.

261, Weiss Allotment
vitals- There are a total of 3839 acres, 2360 are USFS; 1416 AUM's of cattle and sheep. There are no riparian acres.
management aspects- There is an 1987 AMP.

238, Reed Allotment
Vitals There are a total of 3154 acres, 2160 are USFS-; 514 AUM's of cattle and sheep. There are no riparian acres.
management aspects- There is an 1985 AMP, which is out of date; a violation of FLPMA and NFMA.

In order to link these allotments, a few chunks of private lands must be acquired through the Douglas Ranger District land swap program. These 15 pieces of private lands identified are strategic links connecting two big blocks of federal. (Pieces with prairie dog towns were opted for over inhabited areas.)

219, Kettleson Allotment-- The private pieces west of the Old Kettleson Place owned by Iberlin Ranch

201, Alexander - The private piece between Tena Creek and Cow Creek above Windy draw owned by Tillard "55" Limited

246, Rothleutner -The private piece between Meadow Creek and east fork southwest of Rothleutner Ranch

Area Between 238 , Reed and 254 ,Wild Bill - The private piece between Bruce Draw and Tin Can Creek

212, Irwin- The private piece between Beckwith Creek and Wildcat creek owned by Irwin Livestock Company

271 Keeline Allotment-- The private piece on Pipeline 4441 directly west of Wellman Ranch and a piece south of Thunder Creek by the corral; owned by Keeline Ranch Company

262 Gordon Allotment-- The piece of private land east of Lynch Roach and west of Fields draw and the piece between Thunder Creek and Prairie Creek owned by Billie Gordon

010- Kara Community Allotment -- Private piece of land below Cow Camp owned by East Cellers community

270 Ostlund Allotment---Private piece directly west Little RW Creek; ownership unlisted

275 Upper Basin Allotment---Private piece east of the Little Thunder Reservoir; ownership unlisted

228 Mattheson Allotment-- Private piece south of the Birdie Bit Ranch owned by Butch Mattheson

231 Fiddleback and 287 Calamity Gulch Allotments- Private piece on Dry Fork Creek southwest of Dilts Ranch owned by Two Rivers Ranch Inc. and Cannon Land and Livestock.

As these lands are prioritized and acquired, a piece of habitat can be established that is 213, 690 acres of existing federal land plus acreage added after acquisition of private land links. This additional acreage will depend on budget and availibility of federal pieces for trade in outlying isolated areas of the Powder River Basin. State lands, BLM lands and additional private inholdings interspersed in this reserve (see map) can either be swapped with agencies or private owners in exchange for isolated federal blocks on the periphery of TBNG. There is also a possibly for an inter-agency pact between Wyoming, BLM and USFS to manage a "new" TBNG with joint management goals. Eventually, a interim multi-agency pact would allow for incorporation of additional pieces of BLM[22] lands that border Thunder Basin to the east, to create a larger reserve. As the habitat base is established, federal protection in the form of national park, natural resource area, national recreation area, or national monument designation can be sought.

---

[22] BLM land connects with TBNG on the Converse County / Niobrara County Line on the Tenth Standard Parellel

Conclusion

Transition to a Reserve

Whether TBNG can earn legislative protection, or whether protection comes slowly through suits and some lesser federal protection status, the transition should include the following modifications :

1) **Raise resources**. Whatever approach is taken towards developing a reserve, costs will certainly be incurred. Legal and lobbying expenses, community outreach costs, and the expense of restoration and re-introduction will require grants, fundraing and diverted federal subsidizes.

2) **Re-group**. The USFS has to work on a centralized form of management and move to mutually govern lands with the BLM and the State of Wyoming. Since TBNG is a jumble of land ownership, USFS management needs to be cooperative within these agencies.

3) **Re-prioritize**. Livestock should be phased out as public land continuity is established and private inholdings are aquired, with the possibility of compensating ranchers by re-directing grazing subsidies to individual permit holders.[23] Due to the ecological importance of a large grazing herbivore presence in TBNG, bison re-introduction should interpose a livestock phase-out. This process may take a while as bison are expensive and difficult to manage, but as the proper infrastructure is established, phase-out should begin immediately.

---

[23] Federal subsidies cover "range improvements", fencing, stock pond development, weed erradication, and road building. This does not include predator or prairie dog control costs.

4) **Reform**. Management of TBNG should not be focused on resources, but on prairie species conservation and intense re-introduction and restoration. Missing species need to have suitable habitat and then be re-introduced.

5) **Re-populate**. Black tailed prairie dogs population numbers should stand around 10-30 prairie dogs per hecacre (O'Mielia, 1980). As species population re-establish, black-footed ferrets need to be re-established to one mother/pup pair per 30-50 hectarces, with one male overlapping the territories of several females (Harris, et al, 1989). In order to establish a minimum viable population numbers, 120-150 ferrets must exist in a population, connected to other populations throughout TBNG.

Mountain lion, coyote, black bear and studies in TBNG need to establish existing population numbers in order to see if minimum viable populations are already meet. [24]

Although bison management is costly and difficult to maintain, bison re-introduction is essential to an intact prairie ecosystem and favorable to cattle (see Appendix B). Re-introduction may move slowly to replace a cattle phase-out. The bison population should be between 125-193/100 hectacres according to the figures in Badlands (Berger, 1994) and Theodore National Roosevelt National Park (deJong, 1990), similar habitat types to TBNG.

6) **Revegetate.** Vegetation prototypes for healthy northern grasslands (not based on cattle forage prototypes) should be restored on bare overgrazed lands and in patches of crested wheat grass (exotic). A great deal of vegetation shifts

---

[24] There is a population of black bear in the Laramie Peak area. (USFS, 1990)

should occur as livestock grazing is discontinued and native grazers are restored. Riparian revegetation and steam bank reclamation must also be a priority.

7) **Road rip**. Roads can remain until all private inholdings are acquired within the reserve boundary, then only Highway 450, Makey Road and North Lance Creek Road should remain. Road closures, ripping out roads and revegetation should ensue.

8) **Recreation**. There is not one developed camp site on the TBNG. Camp sites along the Powder and Cheyenne River, by bluffs, or in other scenic areas in TBNG should be developed.

Many prehistoric Indian sites exist on TBNG including campsites, lithic scatters, stone circle sites and butchering sites. An interpretative center for Native American history, grassland ecosystems and species would provide insight into the prehistory of TBNG. Recreation facilities, parking lots and road easements should be low impact in design.

9) **Revenue.** Communities should receive help adapting to a tourism based economy in the form of county and State loans. The TBNG covers eight counties that would gleen income from bird and wildlife viewers as well as recreationalists. Hunters and fishermen can expect a better backcountry experience without cattle upsetting water quality, fish and game populations or regional aesthetics. An economic study needs to be completed as soon as possible, to assess the benefits and liabilities to livestock phase-out.

Tourism would benefit communities far more than the amount of revenue grazing fees contribute to plains counties (Popper, 1991).

10) **Research-** The grasslands have been out of balance for over a hundred years. No one alive today has *seen*, let alone understands, the inter-workings of a healthy shortgrass prairie. As restoration and monitoring are integrated into the framework of a TBNG stewardship program, mushroom studies, lichen studies, invertebrate studies and minimum viable population studies of all prairie species have to constantly be in progress. This region needs to work as an ecosystem. Until resource managers know how the grasslands work, an ecosystem balance is an impossibility.

Thunder Basin is only one recovery site in the High Plains in need of relief from mining and grazing. The principles discussed in this document may be helpful in considering protection strategies ultimately used as the building blocks for protective legislation, the High Plains Ecosystem Protection Act. To restore the High Plains to its original functional state, the High Plains Ecosystem Protection Act needs to target the public lands throughout this region: the Niobrara River region in southwest Nebraska; Platte River Country in southeast Wyoming; the BLM lands and the Charles M. Russell National Wildlife Refuge; the Little Missouri Grasslands in Nebraska; and the western wheatgrass prairies of western North Dakota surrounding Roosevelt National Park.

Of course, these are only a few public areas within the High Plains that need restoration; the lands and potential are massive. The High Plains evolved along with herds of thundering bison, acres of prairie dog towns and seas of native grasses. This ecological profusion has earned the plains the distinction of the "American Serengeti." This diversity and abundance is the historic state rather than current form of this ecosystem. Only immediate recovery can salvage the ecological integrity of the High Plains.

Appendix A

Animals Co-occuring with Black Tailed Prairie Dog Towns
(Carlton, 1994)

Mammals

Coyote
Striped skunk
Mink
Long-tailed weasel
Badger
Raccoon
Red Fox
Mule Deer
Pronghorn
Eastern mole
Desert cottontail
Deer mouse
Thirteen-lined ground squirrel
Pocket gopher
Least chipmunk
Grasshopper mouse
American Bison
Plains pocket gopher
White Tailed deer
Western Harvest Mouse
Domestic cattle
Bobcat
Ord's Kangaroo Rat
House mouse
Domestic sheep
Domestic horse
Hispid pocket mouse
Black-footed ferret
White-tailed jackrabbit
Richardson ground squirrel
Wyoming pocket mouse
Southern plains woodrat
Plains cottontail
Least chipmunk
Porcupine
Elk
Spotted ground squirrel
Black-tailed jack rabbit
Northern grasshopper mouse

Birds

Golden eagle
Ferruginous hawk
American Crow
Red-tailed hawk
Swainson's hawk
Marshhawk (Northern harrier)
Prairie falcon
American kestrel
Burrowing owl
Great horned owl
Sage grouse
Blue-winged teal
Mourning dove
Killdeer
Common nighthawk
Mountain plover
Horned lark
American avocet
American coot
American robin
American white pelican
American widgeon
Biard's sandpiper
Baird's sparrow
Bald eagle
Barn swallow
Black-billed magpie
Black crowned night heron
Boat tailed grackle
Brewers blackbird
Brown-headed cowbird
Buff-breated sandpiper
California gull
Canada goose

Chestnut-collared longspur
McCown's longspur
Vesper sparrow
Lark bunting
Western kingbird
Loggerhead shrike
Brown-headed cowbird
Savannah sparrow
Cliff swallow
Snow bunting
Grasshopper sparrow
Great Blue heron
Greater yellowlegs
Herring gull
House sparrow
Lapland longspur
Lark bunting
Lesser prairie chicken
Lesser scaulp
Long billed-curlew
Marbled godwit
McCown's longspur
Mountain bluebird
Northern bobwhite
Northern harrier
Northern oriole
N. rough-winged swallow
Prairie falco
Red-tailed hawk
Ring-billed gull
Rough-legged hawk
Ruddyduck
Savannah sparrow
Scaled quail
Sharp shinned hawk
Short-eared owl
Snow goose
Spaugue's pipit
Turkey vulture
Vesper sparrow
Western kingbird
Yellow-headed black bird
Willet
Common grackle
Wilson's phalarope
Curved-billed thrasher
Double-crested cormorant
Eared greve
Eastern kingbird
Eastern meadowlark
European starling
Gadwall
Gray partridge
Green-winged teal
Great horned owl
Horned lark
Ladder-backed woodpecker
Lark sparrow
Lesser golden plover
Loggerhead shrike
Lesser yellowlegs
Mallard
Misissippi kite
Merlin
Mourning dove
Northern flicker
Northern mocking bird
Northern pintail
Pied-billed grebe
Redhead
Red-winged blackbird
Rock Dove
Sage grouse
Sage thrasher
Say's pheobe
Scissor-tailed flycatcher
Sharp-tailed grouse
Snow bunting
Sora
Swainson's hawk
Upland sandpiper
Water pipit
Western meadow lark

Amphibians

Leopard frog
Tiger salamander
Western toad
Green toad
Woodhouse toad
Great plains narrow mouthed toad
Chorus frog
Plains spadefoot frog
Couch's spadefoot frog

Reptiles

Eastern short-horned lizard
Sagebrush lizard
Red-sided garter snake
Prairie rattlesnake
Yellow mud turtle
Gopher bullsnake
Chihauhua spotted whiptail
Little stripped whiptail
Ornate boxturtle
Lesser earless lizard
Western diamondback rattler
Racerunner
Common gater snake
Texas spotted whiptail

Appendix B

American Bison

(Knowles, 1994)

*It is estimated that prior to European settlement of the plains, bison numbers were anywhere between 30 and seventy million.

*Between 1870 and 1900, the number was reduced to less than 1,000; 65,000 bison exist on ranches, reservations and parks today

* Migration patterns, indicative of the American bison would open.large swathes of land for evolutionary succession. This process would involve the arrival of prairie dogs that were attracted to disturbed areas. This was due to the high visibility of grazed grasslands allowing prairie dogs to watch for predators. *Dogs would turn up 4 tons of earth in a square acre and allow increased water absorption of 700 gallons.* Prairie dogs clipped forbs and left areas seemingly bare however dramatically increased the nutritional content of the grasses along the dog towns. However in studies, cattle grazing on dog towns weigh the same as cattle grazing apart from prairie dog towns. (O'Mielia, 1988)

* Bison also created large holes in the earth called wallows. Wallows turned into ponds or provided upturned soils and manure that became fertile sod. Bison bones provided calcium for plains herbivore

* Plains Indians were mainly farmers prior to the introduction of the horse by Spanish settlers in the mid-1500's The horse didn't influence the Indian populations immediately, but by the 1700's, many northern plain tribes have adopted bison hunting on horse back and became completely dependent on bison meat and hide for tribe existence

* Tribes would follow herds and used fire both to corner bison and to attract bison to fresh, tender new grass that grew subsequent to fires

* With white settlement, Gen. Sherman ordered that all bison be shot, skinned and sold until they were completely gone in the effort to subdue the Indians.

*Bison extirpation was a political objective and was quite easy due to the fact that they made easy targets at 7 ft high; to large to hide; herding behavior allowed hunters to slaughter several at a time

*With the bison disappearing, cattle was introduced in its absence.

Differences between Cows and Bison
(Knowles and Knowles, 1994)

Ecological Characteristics	Bison	Cattle
Mobility	high	low
Home size range	large	small
Grazing strategy	aggressive	passive
Water stress tolerance	high	low
Readily grazes steep slopes	yes/agile	no/clumsy
Requires water	24-96 hr intervals	12 hr intervals
Activity centered on	forage	water
Forage selection	generalist	specialist
Digestion efficiency	high	moderate
Wallows	yes	no
Cold Tolerance	high	low
Forage though snow	yes	no
Require supplemental winter feed	no	yes
Requires help calving	no	yes
Anti-predator behavior	strong	weak
Herding behavior	excellent	good
Longevity	20-30 years	10-15 years
Meat quality	excellent	good

Other Adaptations of Bison

-Bison are ice age animals; ice and snow is not a deterrent in foraging; can forage in snow, massive shoulders and hooves can forage in winter

-Bison are fast and agile and can deal with predators and fires

-Bison are migratory and follow the greening up after storms; do not just camp out like cows (Indians would travel 5-15 miles a day to keep up with the herds)

-Bison can go for 24 hours without water--do not hung out on riparian areas or need stock ponds

-Bison are more agile on treacherous topography

-Bison are general grazers and cattle are selective

-Bison digest prairie grass more efficiency

Bison are wild; cattle are domesticated

-Bison consume more graminoids than cattle--mitigated through historic migrations

-Bison need the prairie ecosystem incorporated with rearing and large pastures that may require multiple owner strategies (private, agency lands)

-Bison do not need predator control or stock pond development or crested wheat grass cultivation

-Bison ranching cannot be focused on maximum net production because as a wild animal bison have to be reared with an ecosystem in mind rather than a controlled operation with fenced pastures

-Bison are field Slaughtered vs. cattle in slaughter house

Appendix C

Grazing Challenge Overview

1)Gila Watch (GW)

Susan Schock; (505) 388-3449/2854; PO Box Silver City, NM

Although Gila Watch is currently involved with several livestock grazing cases, these are representative of GW strategy:

1) *Gila Watch v. US of America, Michael Espy, Jack Ward Thomas, Larry Henson, Regional Forest Supervisor, Carl Pence, Forest Supervisor of the Gila National Forest and Gerald A. Engel, Mimbres District Ranger* (No. Civil 94 1020 MV)

Claim-GW has brought this civil action under 5 USC § 701 et seq. asserting that the Forest Service has violated the *Wilderness Act* (16 USC § 1131, 36 CFR § 219.10 (e) and 36 CFR § 293.2 (1991) by allowing grazing in areas that were not grazed at the time of the establishment of the Wilderness Act.

> "The grazing of livestock shall be permitted where established prior to the date of this Act...." 16 USC § 1131 (d)(4)(2)

Request- That the USFS not grant permits for land not historically grazed prior to the Wilderness Act.

Status- No Decision as yet.

2) *Administrative Appeal on Allotments in Aldo Leopold Wilderness*

Claim- The Forest Service neglected to complete the EIS process on grazing allotments in Aldo Leopold Wilderness; the development of stock tanks in the Aldo Leopold Wilderness violates the Wilderness Act; grazing in riparian regions is an "unsuitable use of the land;" and livestock grazing in the Aldo

Leopold is economically unsuitable(*suitability* -16 U.S.C. § 1603 (g) (2) , 36 C.F.R. § 219.20 and 36 C.R.F. § 219.3).

Request- Assess the economic and ecological *suitability* of the area for livestock grazing and conduct NEPA process on Wilderness area allotments.

Status-No decision as yet.

Issue- USFS on issues of "*suitability*: the appropriateness of applying certain management practices to a particular area of land, as determined by an analysis of the economic and environmental consequences and the alternative uses forgone." (36 CFR 219.3)

2) Oregon Natural Desert Association (ONDA)

Bill Marlett, (503) 385-6908, 16 NW Kansas, Bend, Oregon 97701

ONDA, Rest the West, Oregon Nature Resources Council, Oregon Wildlife Federation, The Pacific Rivers Council, Portland Audubon, and National Trout Unlimited v. USFS

(attorney for ONDA- Michael Axline)

Claim- USFS issued a grazing permit, no. 01607, for the Camp Creek allotment within Malheur National Forest without first requiring the grazing permittee to obtain an Oregon water quality certificate. The action violates section 401(a) of the CWA, 33 U.S.C. § 1341(a).

Request- The USFS require the Cattle Creek Allotment permittee to obtain a state water quality permit before being granted permit renewal.

Status- Motion for summary judgement in April, 1995

Issue- Under Section 401 of the Clean Water Act, federal actions need to insure water standards if permits are issued on public lands. CWA states that an action needs a water quality permit in the case of an activity that "may" cause pollution to a navigable waterway. Evidence that cattle "may cause" pollution has been provided by grazing expert Denzel Ferguson. Jonathan Rhodes, a hydrologist for the Columbia River Inter-Tribal Fish Commission claims that cattle "affects water temperature, erosion, and sedimentation delivery due to its effects on riparian vegetation, soils, and channel morphology. "

The results of this case could be precedent setting and force all grazing permittees that "may pollute" using public lands to obtain state water quality certification . . It also may just become yet another level of bureaucracy.

3) Greater Gila Biodiversity Project (GGBP)

Kieran Suckling; (505) 538-0961; PO Box 742, Silver City, NM 88042

1) *Appeal of Toriette Allotment Management Plan*

Claim- The USFS has classified the renewal of the Toriette AMP a "minor management practice," and has labeled this allotment a "catagorical exclusion."This assertion is without just cause and sufficient scientific data.

The USFS is trying to issue grazing permits without doing an analysis of sensitive species threatening species such as the Apache Trout, Mexican Spotted Owl, and the Gila Trout and thus "fails to consult" under the provisions of ESA.

No cumulative effects analysis has been done on the condition of surrounding allotments as well as the streambank conditions, a process outlined by NEPA. No analysis has been done to determine the effects of "range improvements such as stock ponds and earthen dams.

Request- That the Toriette AMP categorical exclusion classification be reassessed and an injunction on grazing until an EA or EIS is completed on the allotment.

Status- No decision as yet.

Issue-USFS asserts that the revision of the Toriette AMP is an "implementation of a minor management practice to improve allotment condition or animal distribution," and therefore a categorical exclusion (EA documentation, FSH. 1909.15, Chapter 31,2, no. (31.2(9)).

GGBP claims that in making the Toriette Allotment a categorical exclusion, the USFS is violating NEPA, ESA, CWA and the Gila National Forest Management Plan. As yet, there is no ruling on the appeal.

2) *Michael v. District Ranger Steve Gunzel of Tonto National Forest; Supervisor Charles Bazan of the Tonto National Forest; Regional Forester Charles Cartwright and the US Forest Service*

Claim - The decision to re-instate grazing on the Pole Hollow Allotment has been made without consideration of: *suitability* of area for grazing (NFMA 16 U.S.C. § 1604 (g) (2)); reasonable alternatives (NEPA 42 U.S.C. § 4332 (2) (B)); that the decision is "arbitrary and capricious within the meaning of the Administrative Appeals Act" (APA, 5 U.S.C. § 706 (2).

Request- A judgment that the USFS is violating NEPA, NFMA and APA. An injunction on grazing the Pole Hollow Allotment or no more than 112 AUMs yearlong, until the NEPA and NFMA (*suitability* -16 U.S.C. § 1603 (g) (2) , 36 C.F.R. § 219.20 and 36 C.R.F. § 219.3) analysis is completed. No "range improvements" should be developed (fences, stock ponds, pipelines) until NEPA and NFMA are adhered to.

Status- No decsion as yet.

Issue- The Pole Hollow allotment was determined to be in poor condition in range analysis by the USFS and therefore deemed a high priority for legal challenge by the GGBP. In Hells Canyon, the Cayuse, Chalk Creek, Cold Springs, Cow Creek, Dobson Haas, Himmelwright, Mud Duck, Saddle Creek, Rhodes Creek, Schleur, Snell, Temp Sanke and Toomey allotments have been determined in poor condition.These allotments might be the first areas to address when challenging current grazing practices as they may be the most threatened.

4) National Wildlife Federation (NWF)

Tom France (406) 728-6705 240 North Higgins, Missoula, MT 59802

NWF v. USFS

Claim --Range management practices in the Beaverhead National Forest are out of compliance with NEPA (no site specific analysis of 136 of 166 allotments); only 125 allotments met monitoring standards outlined in the Beaverhead Forest Plan; AUMs within Beaverhead AMPs are too high; several riparian areas within the Beaverhead allotments have been classified by USFS to be in poor condition; resource damage from grazing is occurring due to non-compliance with NEPA and NFMA.

The plaintiffs also allege that the USFS is out of compliance with the Administrative Procedures Act (5 U.S.C. § 701 et seq. 1988, PA) that holds federal agencies responsible for action that is "arbitrary and capricious, an abuse of discretion, or otherwise not in accordance with the law" (5 U.C.S. § 706 (2) (A).

Request- An injunction on grazing permits until the Beaverhead allotments go through the EIS process and come up to code with their own Forest Plan.

Status- The NWF offered the USFS ten years to come into compliance with their own laws. The settlement is still being decided. The NWF asked that the USFS do NEPA on 10% of the allotments a year over the 10 year period.

Issue-This case could set a USFS position for revamping AMP development and renewal. A ten year process to update western USFS grazing management policies could take a grave ecological toll on over-grazed federal lands.

5) Joe Feller, University of Arizona Law School/ NWF

(303) 786-8001; 2260 Baseline Road ,#100; Boulder, CO 80309

National Wildlife Federation, Southern Utah Wilderness Alliance and Joe Feller v. Bureau of Land Management (UT-06-93-01)

Claim- *BLM* neglected to notify affected interests (Joe Feller) of a grazing permit renewal to the Ute Mountain Indian Tribe; the BLM neglected to allow affected interests opportunity for public comment on permit renewal; the BLM violated NEPA for not conducting a site specific EIS on five canyons within the Comb Wash allotment within the San Juan Resource Area; the BLM violated *FLPMA* for reissuing a permit without "reasoned and informed decisions of whether the canyon area was in the best public interest to have grazed"; the BLM violated the San Juan Resource Management Plan for setting excessive utilization limits in Comb Wash which was given a "poor" rating in BLM range monitoring.

The BLM disregarded the health and preservation of visual quality, riparian areas, vegetation, recreation use, erosion and wildlife habitat in its decision to graze five canyons within the Comb Wash allotment.

Request- Fence cattle out of sensitive riparian areas until the completion of the EIS on grazing impacts in the Comb Wash allotment.

Status- Case won in 1994; appealed in 1994.

Issue- The San Juan area-wide EIS for its Resource Management Plan did not necessarily apply to the site specific features of canyons and riparian areas within Comb Wash.

Expert witness Robert Ohmart of the Arizona State University gave testimony explaining that the San Juan Resource Area RPM/FEIS "is pathetically short on any understanding or appreciation of efforts to appropriately [sic] manage riparian habitats in the Comb Wash allotment. This document is so generic it could fit any place in northern Arizona or southern Utah if you change the names of the places to protect their identity. That document is meaningless as far as giving anyone any biological assessment of the riparian habitat or wildlife. I mean, there's only four kinds of wildlife in the document. If you aren't a sheep, if you aren't a deer, if you aren't an antelope or a peregrine falcon, you're not even wildlife." (Appeal to BLM of San Juan Resource Area RMP, pg. 9)

TBNG could be challenged for allotments with insufficient NEPA consideration if the area wide EIS for the Wallowa-Whitman Comprehensive Management Plan neglected to address site specific considerations within allotments. In the Feller case, site specific areas that Judge Rampton ruled canyons may need a special site specific NEPA process. Due to their delicate nature, cows were fenced out of two desert canyons in the Comb Wash Allotment.

6) Ochoco Resources and Recreation Association

Tonia Wolf; 281451 Miller Rd.; Prineville, OR 97754;(503) 317-9464

Appeal of Sunflower Grazing Allotment to Regional Forester, Ochoco, NF

Claim- EA on the Sunflower Allotment in the Ochoco National Forest in Eastern Oregon does not consider a "No Grazing" alternative (NEPA)

Request- Full consideration and analysis of a no grazing alternative

Status- Injunction on livestock grazing implemented in 1994; EA completed in 1995. ORRA did not appeal EA.

Issue- As allotments come up for renewal, an EIS or EA must include a no-grazing alternative.

7) Sinapu

Michael Robinson, PO Box 3243, Boulder CO 80307 (303) 494-7920

Administrative Appeal of North Hunt Allotment to Forest Supervisor of the Routt National Forest

Request- Sinapu requests an injunction on grazing on North Hunt until a detailed sustainability study and range analysis are completed.

Claim-The *Finding Of No Significant Impact* (FONSI) classification on North Hunt Allotment is inappropriate because: the allotment is overgrazed; no scientific data exists on wildlife within the allotment boundaries; USFS has failed to consult with the US Fish and Wildlife Service on environmental impacts to the peregrine falcon; the allotment is unsuitable to grazing because of impacts on wildlife, soil, riparian habitat. (According to wildlife biologist Kathleen Nelson, the streambank erosion on Spronks Creek, located within the North Hunt Allotment is "probably the worst in the district.")

(*When the USFS got wind of the Sinapu challenge of cows on North Hunt, the AMP switched cattle AUM stipulations to sheep. Sinapu challenged this switch as illegal under NEPA*).

Sinapu also requests an EIS for the North Hunt drainage complete with analysis on the "effects of livestock grazing on Spronks Creek, its headwaters, and associated riparian areas" (North Hunt Appeal, pg. 3). The EIS needs to include an analysis of land "*suitability*" by examining "the appropriateness of applying certain management practices to a particular area of land, as determined by an analysis of the economic and environmental consequences" (16USC(g)(2);36 CFR 219.20(a).

Status- Appeal was successful and all livestock have been removed from the 6,575 acre North Hunt Allotment.

Issue- The USFS allowed grazing without examining the "suitability" in the EA of North Hunt for livestock. "The first determination--the suitability of the lands for grazing--must be made before a decision to authorize grazing can be made, but a grazing suitability determination does not necessarily lead to a decision to graze those lands. Even though lands may be suitable for grazing, other resource objectives may take precedence over grazing livestock; for example, protection needs of wildlife habitat might take a higher priority in a given area, and thus grazing would be incompatible with this objective" (*Federal Register*, Vol. 59, No. 81, April 28, 1994).

8) National Wildlife Federation (NWF)/Nevada Wildlife Federation,

Peter Frost, National Wildlife Federation, 921 S.W. Morrison, Suite 512, Portland, OR 91184

(503) 222-1429

NWF, Elko County Conservation Association, Nevada Wildlife Federation v. US Forest Service, Jack Ward Thomas, Humboldt National Forest Supervisor R.M "Jim" Nelson

Claim- By allowing livestock grazing on allotments within the Humboldt National Forest, the USFS is in violation of NEPA, NFMA, as well as the Administrative Procedures Act.

Request- Ruling that the USFS is in violation of NFMA, NEPA, and APA. Injunction on grazing until USFS comes into compliance with NEPA and NFMA.

Status- Complaint filed in March, 1995.

Issue- This case is very similar to NWF case in the Beaverhead National Forest (page 12). The appellants, according to Dan Hines (American Wildlands, Reno, NV.) want the USFS to do EIS on Humboldt National Forest grazing allotments, update their AMP, and fence off some riparian areas. As with the Beaverhead case, appellants are willing to allow the USFS months/years to come into compliance.

ORIGINAL PAPER

High prevalence of *Yersinia pestis* in black-tailed prairie dog colonies during an apparent enzootic phase of sylvatic plague

David A. Hanson · Hugh B. Britten · Marco Restani · Leigh R. Washburn

Received: 3 August 2005 / Accepted: 21 September 2006

Abstract Sylvatic plague (*Yersinia pestis*) was introduced into North America over 100 years ago. The disease causes high mortality and extirpations in black-tailed prairie dogs (*Cynomys ludovicianus*), which is of conservation concern because prairie dogs provide habitat for the critically endangered black-footed ferret (*Mustela nigripes*). Our goal was to help elucidate the mechanism *Y. pestis* uses to persist in prairie ecosystems during enzootic and epizootic phases. We used a nested PCR protocol to assay for plague genomes in fleas collected from prairie dog burrows potentially exposed to plague in 1999 and 2000. No active plague epizootic was apparent in the 55 prairie dog colonies sampled in 2002 and 2003. However, 63% of the colonies contained plague-positive burrows in 2002, and 57% contained plague-positive burrows in 2003. Within plague-positive colonies, 23% of sampled burrows contained plague-positive fleas in 2002, and 26% contained plague-positive fleas in 2003. Of 15 intensively sampled colonies, there was no relationship between change in colony area and percentage of plague-positive burrows over the two years of the study. Some seasonality in plague prevalence was apparent because the highest percentages of plague-positive colonies were recorded in May and June. The surprisingly high prevalence of plague on study area colonies without any obvious epizootic suggested that the pathogen existed in an enzootic state in black-tailed prairie dogs. These findings have important implications for the management of prairie dogs and other species that are purported to be enzootic reservoir species.

Keywords *Cynomys ludovicianus* · Disease · Montana · Nested PCR · *Pla* gene

Introduction

Sylvatic plague is caused by the bacterium *Yersinia pestis*, which was introduced into North America from Asia about 100 years ago (Kartman 1970; Perry and Fetherston 1997; Gage and Kosoy 2005). Like other introduced diseases, plague poses a significant threat to native species, particularly those that are rare and endangered (McCallum and Dobson 1995; Thorne and Williams 1988; Woodroffe 1999; Daszak et al. 2000). Plague causes high mortality in black-tailed prairie dogs (*Cynomys ludovicianus*), and is a major factor in the range-wide decline of the species (Biggins and Kosoy 2001; Cully and Williams 2001). Fleas are the primary vectors of sylvatic plague and sociality of prairie dogs facilitates rapid spread of the disease between individuals and among colonies.

Plague has acted in concert with habitat conversion, poisoning, and recreational shooting over the last century to decrease the area occupied by black-tailed prairie dogs by 90–99%, which corresponds to a loss of approximately 40 million hectares of habitat (Anderson et al. 1986; Miller et al.1994; Van Putten and Miller

1999; Forrest 2005). Status of the black-tailed prairie dog is of considerable conservation concern for biologists working to maintain biodiversity because the species creates habitat or is prey for several rare and declining species (Miller et al.1994; Kotliar et al. 1999; Miller et al. 2000). For example, the highly endangered black-footed ferret (*Mustela nigripes*) depends on black-tailed prairie dog colonies for its primary habitat, as do several non-endangered species, including mountain plovers (*Charadrius montanus*), burrowing owls (*Athene cunicularia*), and hawks (*Buteo* spp.) (Knowles et al. 1982; Thorne and Williams 1988; Seery and Matiatos 2000; Restani et al. 2001). Negative effects of plague on prairie dogs indirectly hamper conservation efforts of these species. Black-footed ferrets also suffer a direct effect of plague epizootics because they are highly susceptible to the disease (Williams et al. 1994).

Host species of sylvatic plague are classified as either epizootic (amplifying/susceptible) or enzootic (resistant/reservoir) (Lechleitner et al. 1968; Perry and Fetherston 1997; Gage and Kosoy 2005). In general, resistant hosts transmit the pathogen via fleas to susceptible hosts, thereby triggering an epizootic. It is during epizootic phases that declines in abundance of susceptible species like prairie dogs are observed. Colonies hundreds of hectares in size can be decimated by plague within only a few weeks (Lechleitner et al. 1968; Rayor 1985; Menkens and Anderson 1991; Cully and Williams 2001). In addition to the immediate demographic consequences, these population bottlenecks reduce long-term genetic diversity of prairie dog populations (Trudeau et al. 2004). During the enzootic or maintenance phase, however, there is no widespread mortality in susceptible species and spread of the disease appears highly restricted (Gage and Kosoy 2005).

Epizootic outbreaks of sylvatic plague are typically explained by the presence of resistant reservoir species, which maintain the disease in the environment and are the source of subsequent epizootics in susceptible hosts (Perry and Fetherston 1997; Cully and Williams 2001; Gage and Kosoy 2005). Plague can theoretically be retained in the environment without causing devastating epizootics in susceptible hosts (Keeling and Gilligan 2000; Davis et al. 2004), possibly by cycling within and between reservoir species that are not susceptible to the disease (Barnes 1982). Many common and widespread species are believed to be resistant to the disease, including most carnivores and some rodents (Lechleitner et al. 1968; Barnes 1982; Perry and Fetherston 1997; Biggins and Kosoy 2005). Diseases with purported reservoir hosts are not constrained by the density of their epizootic hosts, which extirpates these populations, yet allows the disease to persist in the environment in enzootic hosts (Barnes 1982). Mitigating plague's effects on the prairie dog ecosystem is proving difficult due its unpredictable and recurrent nature and the distribution and abundance of both susceptible and resistant hosts (Davis et al. 2004).

Montana contains large areas important for conservation of black-tailed prairie dogs and their habitat associates. Colonies occupy an estimated 36,000 hectares, most of which are located in the north-central part of the state (Faunawest Wildlife Consultants 1999). Here colonies are separated by short distances and vary widely in overall size and population density. Our study area, the Fort Belknap Indian Reservation (FBIR), resides within this region and contains about 200 prairie dog colonies as well as reintroduced black-footed ferrets, mountain plovers, and burrowing owls. Fleas from prairie dog burrows on two colonies tested positive for sylvatic plague in 1999, a discovery which coincided with disappearances or significant declines of colonies in 1999 and 2000. Of the 8 flea species common to FBIR, about 70% of the flea fauna is composed of *Oropsylla hirsuta* and *O. tuberculata cynomuris* (Young unpublished data), which feed exclusively on prairie dogs (Cully and Williams 2001). *Pulex irritans* has a wide host preference and constitutes about 15% of the flea assemblage (Young unpublished data).

Collecting and testing fleas for the presence of *Y. pestis* is a potential tool in the surveillance of sylvatic plague. *Y. pestis* accumulates in the foregut of infected fleas (Perry and Fetherston 1997), and PCR-based methods provide a useful and sensitive means to detect the pathogen (Englethaler et al. 1999). We used a very sensitive PCR procedure to detect the presence of *Y. pestis* genomes within fleas collected from black-tailed prairie dog burrows on FBIR in 2002 and 2003. Our goal was to help elucidate the mechanism *Y. pestis* uses to persist in the prairie ecosystem during enzootic and epizootic phases by testing fleas collected from prairie dog colonies that had potentially been exposed to plague in 1999 and 2000.

Methods

Sample collection and DNA extraction

Between May and August 2002 and 2003, we collected fleas from burrows of 55 black-tailed prairie dog colonies on FBIR. We collected fleas by pushing a white flannel cloth into active prairie dog burrows (Ubico et al. 1988). Burrows were determined to be active by the presence of fresh droppings and diggings. Fleas were removed from the cloth and stored in 3.6 ml cryotubes filled with 95% ethanol. We did not identify fleas to species and pooled all fleas sampled from a burrow on each sampling occasion for DNA extraction and plague assays. Sampled burrows were distributed throughout the extent of each colony, and we took a GPS location at each burrow. We sampled 36 colonies at least once during both years of study.

The perimeters of 15 colonies were mapped with GPS technology from 2001 to 2003 (Geoscience Associates 2003), and we extensively sampled these 15 colonies for fleas throughout 2002 and 2003: late May/early June, late June/early July, and late July/early August. We sought to associate any change in area of the prairie dog colony with seasonal prevalence of plague**.** Following convention, we used area of prairie dog colonies as an index to abundance (i.e., population size) (Miller et al. 1994; Van Putten and Miller 1999; Cully and Williams 2001; Forrest 2005). Study colonies were selected based on previous declines in size suggestive of past plague epizootics or their proximity to infected colonies.

We extracted DNA from whole fleas with the Easy DNA kit (Invitrogen Life Technologies, Carlsbad, CA). Manufacturer's protocols were followed in modified form for mouse tail extraction (protocol 8, Invitrogen Life Technologies) using 0.1 of the recommended volume. Fleas were washed in 0.15% saline solution, added to 1.5 ml micro-centrifuge tubes, and crushed with a closed 1000 µl pipette tip. A chloroform extraction followed as described by the manufacturer. Supernatant was washed with 100 µl of 100% ethanol (–20°C) and set on ice for 30 min. Centrifugation followed at maximum speed for 10min at 4°C. We decanted ethanol and dried the resulting pellet in a vacuum centrifuge. The pellet was resuspended in 30 µl of TE and stored at –70°C.

Bacterial strains and cultivation

We obtained *Y. pestis* strain A1122 var. *orientalis* from the Centers for Disease Control, Ft. Collins, CO. This strain lacks the 70-kb pCD1 virulence plasmid and is not pathogenic. *Y. pseudotuberculosis* (ATCC #29833) and *Y. enterocolitica* (ATCC #23715) were obtained from the American Type Culture Collection. Cultures were grown in Brain-Heart Infusion (BHI) broth with agitation at 37°C. We stored 1-ml aliquots from overnight broth cultures at –70°C. Counts were performed to determine total numbers of colony-forming units (CFU) in each stock culture. Total genomic DNA was extracted using Easy-DNA (Invitrogen Life Technologies) from ~1.3×10^7 CFU *Y. pestis*, 4×10^9 CFU *Y. pseudotuberculosis*, and 3.2×10^9 CFU *Y. enterocolitica*; CFU:bacteria ratio for *Y. pestis* is probably <1 due to the tendency of this organism to clump in broth medium. DNA was dissolved in 50 µl tris-EDTA (TE, 10 mM tris-HCL pH 8.5/1 mM EDTA).

Nested PCR

A nested PCR, based on an assay described by Hinnebusch and Schwan (1993), was designed to amplify a 110-bp fragment of the plasmid-encoded *pla* (plasminogen activator) gene unique to *Y. pestis* (Sodeinde et al. 1988). A nested PCR protocol was used because the desired sensitivity could not be achieved with a single primer set. All PCRs were carried out using either a MJ Research PTC 200 Thermocycler or an Eppendorf Mastercycler Personal Thermocycler. The initial step was carried out using primers ypl3 and ypl4 (5′–3′ catccggctcacgttattatggtacc, 5′–3′ ctgtaggaagctcaacatccaag) modified from primers yp1 and yp2 described by Hinnebusch and Schwan (1993), in a 50 µl reaction containing 1 Hotstart *Taq* Polymerase bead (Promega Taqbead 1.25 u/bead), 1× $MgCl_2$ free buffer, 0.2 mM dNTP, 1.5 mM $MgCl_2$, 1.0 µM primers. Settings were 1 cycle at 95°C for 5 min, 30 cycles at 95°C for 1 min, 50°C for 1 min, and 72°C for 2 min, 1 cycle at 72°C for 8 min. This initial PCR product was 460 bp in length. Nested PCR used primers ypl5 and ypl6 (5′–3′ cacacctaatgccaaagtct-ttgcgg, 5′–3′ gtggagattctgtctctattggcg). Nested PCR was carried out by using 5 µl of product from the initial PCR step in a 50 µl reaction containing the same concentration of reagents and subjected to the same conditions as the initial PCR step. Sensitivity and specificity of the assay were determined by amplifying 10-µl templates of 10-fold *Y. pestis* DNA dilutions and 10 µl 1:10 dilutions of *Y. enterocolitica* and *Y. pseudotuberculosis* DNA. PCR products were examined by electrophoresis on 1.5% or 2% TBE agarose gels stained with ethidium bromide. Gels were photographed with an electrophoresis documentation system (Kodak Electrophoresis Documentation and Analysis System 120). Amplification of the *pla* fragment from *Y. pestis* DNA extracted from fleas was carried out with 5 µl of undiluted template. DNA extracted from *Y. enterocolitica* and *Y. pseudotuberculosis* and sterile water (5 µl each) were used as negative controls, and DNA extracted from *Y. pestis* strain A1122 and diluted 10^{-6} (5 µl) was used as a positive control in all PCRs.

Later, one negative and several positive flea DNA samples and the above-described positive and negative controls were reamplified to provide an example of assay results (Fig. 1); for this purpose we used 1 µl of template and electrophoresed the resulting amplicons on a 2% agarose gel.

Results

Y. pestis DNA diluted 10^{-1} through 10^{-6} yielded 110-bp products. In a later experiment, similar results were obtained with 1 μl of the 10^{-6} dilution (Fig. 1), for an apparent sensitivity of ~0.3 CFU per sample (actual sensitivity is less than this because of bacterial clumping and the likely presence of multiple copies of the *pla*-encoding plasmid per *Y. pestis* genome). No products were amplified from *Y. enterocolitica* or *Y. pseudotuberculosis* at any concentration tested. These results confirm that the nested PCR used in this study is both specific and highly sensitive.

We sampled fleas from 55 colonies in 2002 and 2003, with 36 colonies sampled at least once both years (Table 1). Fig. 1 shows a sampling of *pla* amplicons from fleas collected in this study. Overall, 63% (n = 30 colonies) of colonies had at least one plague-positive flea sample in 2002, and 57% (n = 24 colonies) of colonies had at least one plague-positive flea sample in 2003. Plague-positive colonies were distributed throughout FBIR. For plague-positive colonies, 23% (mean ± SE, 3.9 ± 0.5 plague-positive burrows/colony) of sampled burrows had plague-positive fleas in 2002, and 26% (2.3 ± 0.3 plague-positive burrows/colony) had plague-positive burrows in 2003.

We collected fleas from 15 colonies over 3 time periods in 2002 and 2003 (Table 2). Although percentages of plague-positive colonies varied among the 3 sample periods, plague was most detectible between late May and early July (Fig. 2). These results were also consistent with the entire dataset: for all plague-positive burrows sampled in 2002, 72% were from late June/early July, and 72% of all plague-positive burrows sampled in 2003 were from late May/early June.

Of the 15 intensively sampled colonies, 4 colonies increased in area (ha) between 2001 and 2002, and between 2002 and 2003 (Table 3). Six colonies decreased in area between 2001 and 2002, and a different group of five colonies decreased in area between 2002 and 2003. No colony decreased in area both years. Of the 15 intensively sampled colonies, a regression of percentage change in colony area between 2001 and 2002 against percentage of plague-positive burrows in 2002 was nonsignificant ($r^2 = 0.207$, $F = 3.38$, df = 14, $P = 0.09$). A similar nonsignificant result was obtained for colony area changes between 2002 and 2003 ($r^2 = 0.028$, $F = 0.371$, df = 14, $P = 0.55$).

Discussion

Results of our study indicate that, under some conditions, reservoir species may be unimportant in maintaining sylvatic plague in an enzootic state in the prairie dog ecosystem and that some black-tailed prairie dogs may be enzootic hosts of the pathogen. First, an unexpected high percentage (57–63%) of prairie dog colonies tested positive for *Y. pestis*. Wide distribution and high prevalence of plague-positive fleas on FBIR was not an artifact of sampling because we collected fleas from dozens of colonies across a large geographic area (ca 50 km×80 km). Second, despite high prevalence of plague-positive fleas, there was no evidence of an ongoing epizootic, which would have been manifest in significant and consistent declines in the area of prairie dog colonies (Van Putten and Miller 1999; Cully and Williams 2001; Trudeau

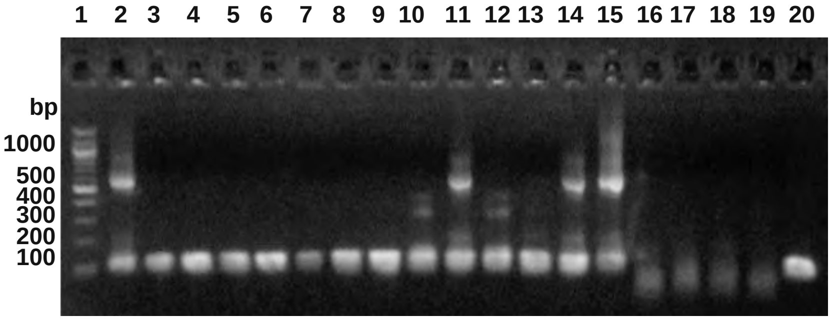

Fig. 1 Nested PCR results from selected flea samples. 1-μl samples were amplified as described in Materials and Methods; 5 μl each were electrophoresed on a 2% agarose gel. Table 1 Sampling effort of flea collection and results of PCR-based sylvatic plague assays from black-tailed prairie dog colonies on the Fort Belknap Indian Reservation, Montana, 2002 and 2003. Results are mean ± SE

Year	Number of colonies sampled	Number of burrows sampled/colony	Number of fleas collected/colony	Number of fleas collected/burrow	Number of plague-positive colonies	Number of plague-positive burrows/colony
2002	48	10.9 ± 0.9	17.6 ± 1.9	1.5 ± 0.1	30	3.9 ± 0.5
2003	42	6.6 ± 0.6	8.5 ± 0.8	1.5 ± 0.1	24	2.3 ± 0.3

et al. 2004; Pauli et al. 2006). Prairie dog colonies fluctuated in size from 2001 to 2003, with some individual colonies both increasing and decreasing across years. Third, we collected fewer fleas from individual burrows than reported by previous studies which sampled fleas during ongoing epizootics (Lechleitner et al. 1968; Ubico et al. 1988; Cully et al. 2000). Low flea activity on FBIR provided further support that no epizootic occurred in 2002 and 2003. In sum, we failed to observe the widespread declines of colonies that would have been expected if reservoir species acted solely to maintain plague and if black-tailed prairie dogs were strictly an epizootic host.

Most studies implicate reservoir species as maintaining sylvatic plague in the prairie dog ecosystem between epizootics (Rayor 1985; Ubico et al. 1988; Menkens and Anderson 1991; Anderson and Williams 1997; Cully and Williams 2001). However, alternative mechanisms have been proposed for plague maintenance in other rodents and these mechanisms may pertain to black-tailed prairie dogs as well. For example, Keeling and Gilligan (2000) modeled plague persistence in rat metapopulations and reported that plague could exist enzootically even when 50% of the rat population was susceptible. Epizootics occurred when >80% of the rat population was susceptible. Enzootic maintenance of plague also occurs in Asian rodent populations such as great gerbils (*Rhombomys opimus*) where plague is native (Davis et al. 2004). These theoretical and empirical results suggest some parameters by which the disease can be maintained in an enzootic phase within a susceptible rodent host such as the black-tailed prairie dog (see also Webb et al. 2006). Black-tailed prairie dogs might also exhibit greater resistance to the disease than is currently believed (Pauli et al. 2006). Although sylvatic plague has been in North America for only 100 years, some degree of resistance could evolve within decades (Altizer et al. 2003). This possibility exists for black-tailed prairie dogs because populations typically harbor high levels of genetic diversity (Chesser 1983; Daley 1992; Altizer et al. 2003).

Poor vector to host transfer of the disease is also a possible explanation for the high level of plague found in fleas at our site. Different species of fleas have been shown to vary in their ability to transmit the disease, with the highest level of transmission seen with the rat flea *Xenopsylla cheopis* (Burroughs 1947; Holdenried 1952). *O. hirsuta* and *O. tuberculata cynomuris* are the most common fleas inhabiting black-tailed prairie dog burrows at our site and may be important vectors. Although their ability to transfer plague has not been extensively studied, recent evidence from Hinnebusch et al. (1998) indicates that *Y. pestis* may not replicate to high enough numbers in *O. hirsuta* to readily create the "blocked" condition required for transmission. These investigators observed that while 48% of *O. hirsuta* fleas collected from a prairie dog colony after a plague outbreak were positive for *Y. pestis*, <2% carried sufficient numbers of bacteria to be considered "blocked." This is consistent with our observation that larger numbers of fleas were PCR positive in this study

Table 2 Sampling effort of flea collection and results of PCR-based sylvatic plague assays from 15 intensively sampled black-tailed prairie dog colonies on the Fort Belknap Indian Reservation, Montana, 2002 and 2003. Results are mean ± SE

Sample period	Number of burrows sampled/colony	Number of fleas collected/colony	Number of fleas collected/burrow	Number of positive burrows/positive colony	Percentage positive burrows

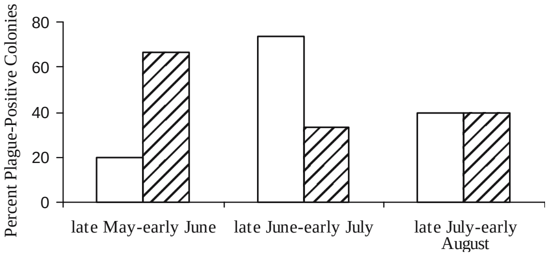

Fig. 2 Percentage of 15 black-tailed prairie dog colonies containing plague-positive fleas on the Fort Belknap Indian Reservation, Montana, 2002 (open bars) and 2003 (shaded bars)

than would have been predicted by the apparent overall health of the prairie dog colonies. Conditions under which transmission of plague begins are not understood but contributing factors likely include enhanced replication of *Y. pestis* in fleas (or higher levels of bacteremia in host animals, leading to uptake of more CFU in a blood meal [Hinnebusch et al. 1998]), greater flea infestation levels, and possible changes in susceptibility or resistance of the resident rodent population.

Although sylvatic plague did not appear to be intensifying or declining from 2001 to 2003 on FBIR, it appeared that some amplification had occurred seasonally. The late June/early July 2002 sample period showed a noticeable increase in the percentage of plague-positive burrows, whereas a similar increase occurred in late May/early June 2003. These effects were no longer apparent by late July/early August of both years. Thus, there may be as yet unknown seasonal factors that participate in the dynamics of plague at our study site.

Table 3 Area (ha) and percentage change in area of 15 intensively sampled black-tailed prairie dog colonies on the Fort Belknap Indian Reservation, Montana, 2001 to 2003

Colony	Area in 2001	Area in 2002	Percentage Change 2001 to 2002	Area in 2003	Percentage Change 2002 to 2003

126	17	4	–77	7	77
127	39	2	–95	3	33

Sylvatic plague is the only disease known to threaten black-tailed prairie dog populations with high mortality and local extirpation (Anderson et al. 1986; Miller et al.1994; Biggins and Kosoy 2001; Cully and Williams 2001; Pauli et al. 2006). *Y. pestis* is retained in the environment and can cause recurrent unpredictable epizootics, adding to the devastating nature of the disease on native biodiversity. The pathogen's reliance on reservoir hosts during enzootic periods is thought to be an important ecological aspect of the disease. Moreover, prairie dogs are thought to lack any immunity to the disease. Our highly sensitive PCR-based technique detected the pathogen in fleas collected from black-tailed prairie dog burrows during an enzootic phase. Thus, our technique could be used to screen currently healthy black-tailed prairie dog colonies that are being considered for black-footed ferret re-introductions and potentially to predict future plague epizootics in such colonies. Clearly, further basic research into the means by which sylvatic plague is maintained in the environment over enzootic periods is needed. Such research would also benefit conservation programs devoted to maintenance of black-tailed prairie dog populations and their habitat associates.

Acknowledgments We thank the Assiniboine Tribal authorities for granting permission to conduct research on the Fort Belknap Indian Reservation, Montana. Our work received logistical support from G. Kaiser, U.S. Bureau of Indian Affairs. P. Young kindly shared unpublished data and insight on prairie dog ecology. J. Weigand generously allowed DH the use of his property as a field camp. We thank an anonymous reviewer and Associate Editor for their useful comments on the manuscript. Partial funding was provided by the Nelson Foundation and the University of South Dakota Office of Research. This material is based upon work supported by the National Science Foundation/EPSCoR Grant No. 0091948 and by the State of South Dakota.

ACKNOWLEDGMENTS

The success of this study is due to the cooperation of many persons, agencies and organizations. The publication is a joint contribution of the South Dakota Cooperative Wildlife Research Unit, Brookings; the South Dakota Department of Game, Fish and Parks; South Dakota State University, U. S. Bureau of Sport Fisheries and Wildlife, and the Wildlife Management Institute.

We particularly want to acknowledge the assistance of Robert A. Hodgins, director of the South Dakota Department of Game, Fish and Parks, who encouraged and supported the publication of the results of this study; Walter H. Kittams, National Park Service, who maintained interest in black-footed ferrets prior to the initiation of this study and provided past records he had accumulated and arranged for the financial support of his agency; William N. Pullins, Bureau of Sport Fisheries and Wildlife, who called attention to the first ferret on which this study was based and provided information on other ferret sightings; and to the various ranchers, particularly Earl Adrian and James Carr of White River, South Dakota, who permitted study of ferrets on their lands or supplied information on ferret sightings.

Others who contributed in various ways include: Fred Priewert, B. J. Rose, Floyd Vogelgesang, Douglas R. West, W. Glenn Titus, Warren Jackson, Robert Morris, and district game managers and game wardens of the South Dakota Department of Game, Fish and Parks; personnel associated with the South Dakota Cooperative Wildlife Research Unit, including Conrad N. Hillman, Raymond L. Linder and Robert B. Dahlgren; Donald K. Fortenbery, A. Orville Sandall, Van T. Harris, Ray C. Erickson, Richard H. Manville, John L. Paradiso, Lee E. Yeager, and district field assistants of the Bureau of Sport Fisheries and Wildlife; Robert Powell and Frank A. Hjort of the National Park Service; Donald R. Progulske of South Dakota State University; Clarence Cottam of the Welder Wildlife Foundation; E. Raymond Hall of the University of Kansas Museum of Natural History; the Badlands Natural History Association; Warren E. Garst of Chicago, Illinois; and Ralph Hubbard of Medora, North Dakota.

To all others who provided information of ferrets or who helped in other ways we also are indebted.

The senior author, F. Robert Henderson, was a district game manager with the South Dakota Department of Game, Fish and Parks at Kadoka at the time of the study; he is now an extension specialist, Wildlife Damage Control, Kansas State University, Manhattan. Paul F. Springer was formerly leader of the South Dakota Cooperative Wildlife Research Unit, U. S. Bureau of Sport Fisheries and Wildlife, at Brookings. At present he is biologist-in-charge of the bureau's Migratory Bird Research Station, Arcata, California. Richard Adrian was a field assistant under the unit and now resides at Grosse Pointe Farms, Michigan.

INTRODUCTION AND PURPOSE

Since 1851, when the mammal shown in Figure 1 was first described as a separate species and named the black-footed ferret **(Mustela nigripes)** by naturalists John J. Audubon and John Bachman, it has remained hidden behind its mask. Speculation about its behavior patterns and life history has rarely been verified. In fact, human observation of the ferret was so infrequent that in 1964, when the U. S. Bureau of Sport Fisheries and Wildlife compiled its first published list of rare and endangered wildlife, the black-footed ferret was one of the species included.

Not only has the black-footed ferret been seen rarely, but it has been referred to in published material only incidentally. The principal literature on the species is limited to description of its physical appearance and habitat. No detailed or definitive studies on life history and ecological relationships are available. Little of the usual behavior which we observed has been reported in the literature, and some reports have proved to be in error. This leads to one inescapable conclusion — a scarcity of first-hand ferret observations in the past.

On August 7, 1964, while checking prairie dog colonies in Mellette County, South Dakota, William N. Pullins, district field assistant of the U. S. Bureau of Sport Fisheries and Wildlife, observed a black-footed ferret. Pullins was accompanied by the landowner's son, Richard Adrian. Subsequently, Adrian observed at least eight other ferrets in this town and in another 3 miles north.

Because of the unique opportunity to learn more about the black-footed ferret, arrangements were made for Adrian to begin regular observations of the animals under the auspices of the South Dakota Cooperative Wildlife Research Unit. These studies extended from August 17, 1964, through August 31, 1965. F. Robert Henderson made many additional observations throughout this and a subsequent period. Paul F. Springer supervised the over-all effort through June 1967, made observations, and helped to arrange for financial support by the Bureau of Sport Fisheries and Wildlife, the National Park Service, the Welder Wildlife Foundation, and the Badlands Natural History Association. Further field studies under the Cooperative Wildlife Research Unit were conducted from April 1966 to December 1967 and published separately by research assistant Conrad Hillman (1968).

Initially, the intent of the study was twofold: (1) to determine the distribution and status of the black-footed ferret in South Dakota, and (2) to gather information on its life history, behavior and ecology. As the study progressed, another objective was added: (3) to develop techniques for locating black-footed ferrets.

The present account records information gathered by the authors to June 1968. We believe this report of initial findings will be useful to others who want to learn more about this little known mammal. We hope this report will also be instrumental in encouraging more widespread and intensive investigation into the ecology and preservation of this elusive species.

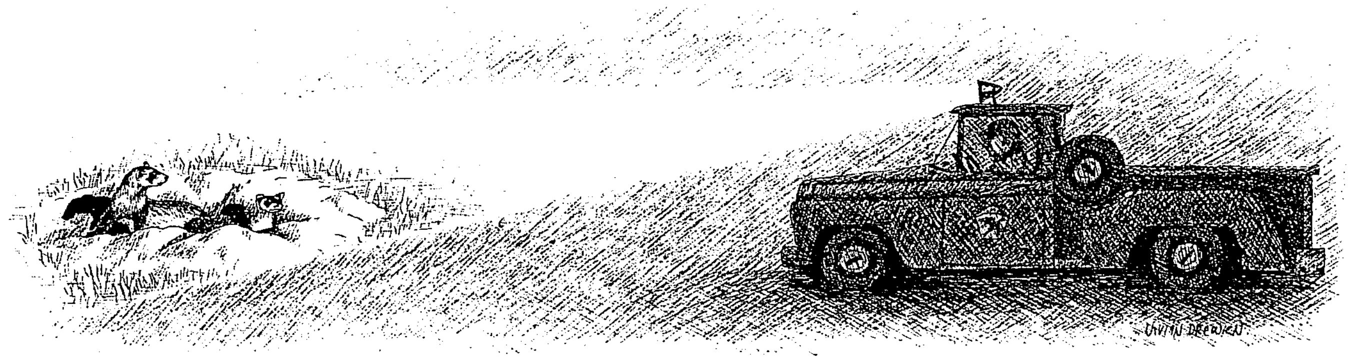

Figure 2. Observing ferrets at night with a spotlight.

METHODS

After the initial ferret sighting in August 1964, the two prairie dog towns were put under intensive surveillance both day and night. Observations were facilitated by the use of 7X binoculars and 15X spotting scope. Nocturnal observations were made by using several types of spotlights with various colored filters. The most effective was a 100-watt aircraft landing light mounted on top of a truck cab or placed in a portable navy signal light housing and plugged into a cigarette lighter socket (Figure 2). An army snooper-scope (Model IX) was also tested but found to be unsatisfactory because of low magnification and poor definition. Observations made in the field were recorded on magnetic tape or in notebooks and later transcribed to a journal.

In addition, several experiments on behavior, explained later in this report, were conducted at the study locations. All field observations were recorded in Standard Time.

In conjunction with its landowner game questionnaire the South Dakota Department of Game, Fish and Parks included a postcard with a color photograph of the black-footed ferret. These were sent to all ranchers in the state west of the Missouri River except Corson, Ziebach, Dewey and Stanley Counties. Information gained from this questionnaire aided in obtaining records of many additional black-footed ferrets. The cost of printing the postcard was paid for by the Badlands Natural History Association.

While conducting annual aerial antelope censuses and engaging in other activities, Department Game Division personnel plotted prairie dog towns on maps. Many of these towns were later visited by the authors in search of black-footed ferrets.

A thorough survey was made of published and unpublished literature on the black-footed ferret and the black-tailed prairie dog, with particular reference to South Dakota. In addition, all museums likely to have specimens of black-footed ferrets were visited or contacted, and examination was made of many of the specimens in their collections.

Throughout the report all county locations mentioned are in South Dakota unless otherwise indicated.

INDIAN RELATIONSHIP

Although a mystery to the white man, the black-footed ferret was known to the Plains Indian. According to the Sioux, their name for the ferret is "pispiza etopta sapa," meaning "black-faced prairie dog" (Vetal Romero and Leo Cadotte **pers. com.**). In the sign language of the Plains Indian the symbol for the ferret is Z. It is represented by an arm held up with elbow and wrist crooked. The person making the motion then points at something black and passes his hand across his face or holds up his hands (Ralph Hubbard **pers. com.**).

The ferret was also held in special regard by the Indian. In Montana the Blackfeet (Homolka 1964) and Cheyennes (Ralph Hubbard **pers. com.**) once used the tawny hides of the black-footed ferret as pendants on chiefs' headdresses. Peterson and Berg (1954) reported four black-footed ferret skins preserved in a collection of Indian relics at Pryor, Montana. The skins, which had been collected and stuffed by Crow Indians many years ago, were used in ceremonies. In the Indian museum at St. Francis, South Dakota, a collection of relics prepared by a Sioux to represent his native traditions includes two complete ferret skins in a display of sacred tribal objects. Leo Cadotte **(pers. com.)** points out that medicine men included ferret pelts among their medical paraphernalia as a symbol of influence when ministering to their patients.

There is no evidence that Indians have used ferrets in headdresses (Homolka 1964) or other ceremonial items for many years. Undoubtedly this is due in part to a general breakdown in Indian culture resulting from the formation of reservations.

Indians also had other uses for the ferret. A whole skin said to have come from the Sand Hills of Nebraska was used by Indians as a tobacco pouch (Vernon Bailey **unpubl. rept.**). Ferrets captured by Indians were reported to be eaten and considered a delicacy (H. H. Haecker **unpubl. rept.**).

The Pawnees of Nebraska knew the ferret as the "ground dog." They believed that if it sat up and looked at a person, meanwhile working its jaws as if chewing, the entrails of that person would at once be cut to pieces and he would die

(Grinnell 1895). The Sioux had various beliefs about the ferret. Some thought that anyone who killed a ferret would have bad luck (Vetal Romero **pers. com.**) or would be hypnotized (Leo Cadotte **pers. com.**). Others believed that a person would suffer no harm if he shot and killed a ferret, but would become ill if he missed or if he did not shoot (Bryan Provancial **pers. com.**). H. H. Sheldon (**unpubl. rept.**), writing in 1915, stated that ferrets in northern Shannon County were often killed by Indians.

PHYSICAL DESCRIPTION

The ferret was first described by Audubon and Bachman (1851) on the basis of an imperfect skin sent to them by naturalist Alexander Culbertson from the Fort Laramie, Wyoming, area (Hall and Kelson 1959). Subsequent collections have provided a more detailed description.

The most obvious distinguishing feature is the striking black mask across the face (Figure 1). The feet, legs to the shoulders and terminal fourth of the tail are also black. The remaining pelage is a pale yellow-buff becoming lighter on the under parts of the body and nearly white on the forehead, muzzle and throat. The top of the head and middle of the back are brown. The fur is short — about two-fifths of an inch in length on the back.

Young ferrets are lighter in color than are adults (Aldous 1940, Hillman 1968). We believe the pelage to be slightly paler in the male than in the female. We also observed in the field that most males have a black to black-brown longitudinal stripe in the pubic region, a characteristic that is faint or lacking in the females. This marking perimts field identification of sexes when the animals stand.

Springer checked this marking in the U. S. National Museum on 51 specimens that had been sexed (33 males and 18 females). The only exception from the rule were two specimens labelled male that did not have the stripe and one specimen labelled female that had a noticeable stripe. In the case of the males the stripe could have been sewed inside or trimmed off when the study skins were prepared.

Figure 3. Typical view of a black-footed ferret peering from a prairie dog burrow. Mellette County, South Dakota, July 28, 1966. (Rose)

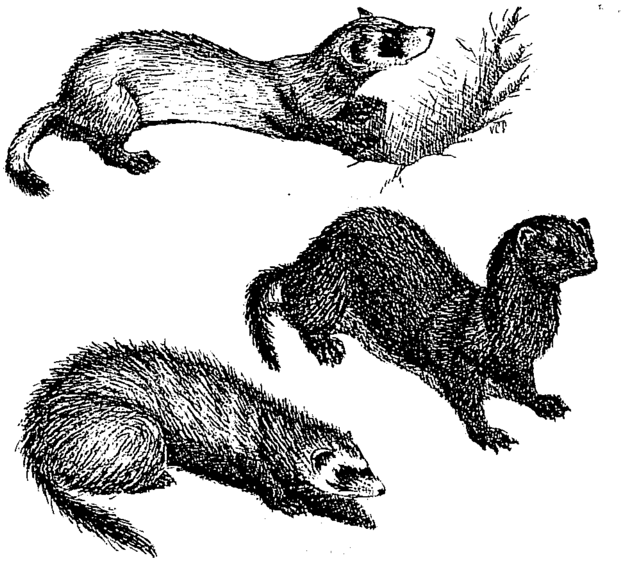

Figure 4. Black-footed ferret, mink and European fitch ferret.

Ferrets do not molt to a white coat in the winter as do some members of the genus **Mustela** in colder climates. Hall and Kelson (1959) state that the pelage may become slightly paler in winter. Our examination of museum specimens also indicates the winter pelage is slightly longer. The color of the ferret blends well with that of the soil in many prairie dog towns and may serve as a means of camouflage. Ferrets are most commonly observed peering out of a burrow with only their heads visible (Figures 2 and 3). In this posture the black mask obscures the form of the ferret and makes it difficult to distinguish. Probably the black mask has an additional function of reducing glare from light-colored soil or snow.

Ferrets are similar in size and weight to wild mink. Adult male ferrets are 21 to 23 inches in total length. Two males weighed 2 pounds 2 ounces and 2 pounds 6 ounces, respectively (Burt and Grossenheider 1964:62), and two females weighed 1 pound 11 ounces and 1 pound 14 ounces, respectively (see Page 36, records 212 and 215). A captive male varied in weight from 2 pounds, 11 ounces to 3 pounds, 3 ounces (D. R. Progulske **unpubl. MS.**).

Ferrets are short-legged, have long well-developed claws on the front paws, large ears and relatively large eyes. After dark the ferret's eyes show a green reflection in artificial light.

The native black-footed ferret should not be confused with the domestic European fitch ferret (Figure 4), which is descended from the European polecat. The domestic fitch ferret differs from the black-footed ferret in having longer and darker pelage on the back, yellowish underfur, and an entirely black tail. It was used for rodent control by the colonial settlers on their voyages across the Atlantic and has been employed for this purpose on farms. This is the animal that formerly was used for rabbit hunting. The domestic ferret rarely if ever becomes established in the wild.

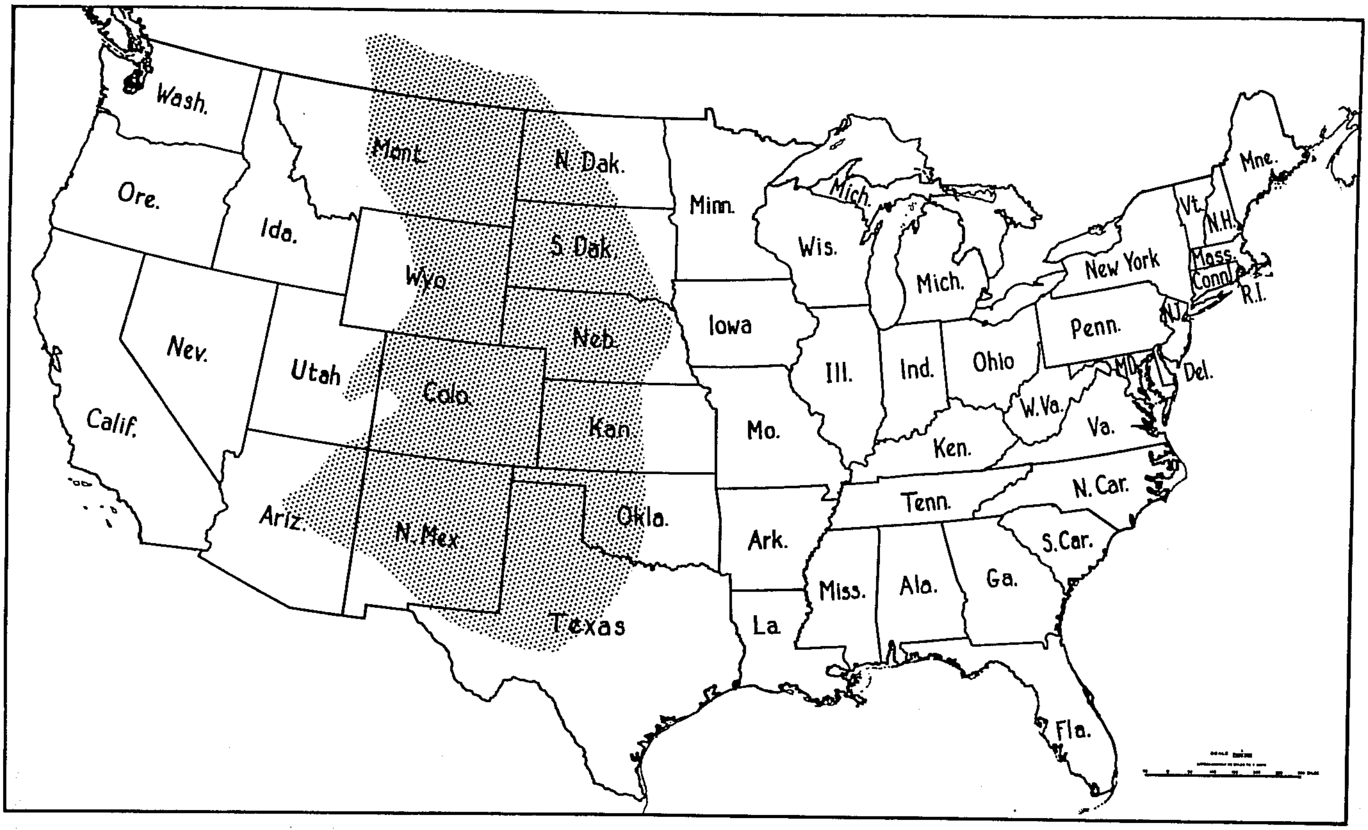

Figure 5. Former range of the black-footed ferret. (Hall and Kelson 1959)

HABITAT

The black-footed ferret is characteristic of the short and mid grass prairies, originally occurring from southern Alberta and Saskatchewan south to Arizona and Texas (Figure 5). Ferrets have been found living in haystacks, under buildings, and in ground squirrel colonies. The majority of evidence, however, indicates their principal natural habitat, at least in the northern part of their range, is prairie dog colonies. The historical geographic range of the black-footed ferret nearly coincided with the combined ranges of the black-tailed and white-tailed prairie dogs (Seton 1929, Burt and Grossenheider 1964).

The black-tailed prairie dog (Figure 6), the only species of prairie dog in South Dakota, lives in colonies or "towns." In the western part of the state these towns are typically on gentle slopes or level ground of clay and silt soils, primarily of the Chestnut zonal group. Average precipitation in this area varies from 13 to 19 inches annually (Westin et al. 1959). The grasses associated with this soil type are short grasses, including buffalo grass, blue grama, western wheatgrass, and green needlegrass, interspersed with patches of forbs. The burrow is the home of the prairie dog, and his feeding and digging activities favor the growth of forbs, many of which he eats (Figure 7). By cutting down these plants, prairie dogs provide themselves with a wide view. This enables them to scan the area for predators before leaving the protection of their burrows. Cutting down taller plants also favors the growth of short grasses, mainly buffalo grass and blue grama, which are among the staple foods of the prairie dog (Koford 1958).

Figure 6. Black-tailed prairie dogs at entrance of burrow. Shannon County, South Dakota, August 1966. (Henderson)

Figure 7. Prairie dogs feeding.

DISTRIBUTION AND STATUS

The ferret has never been considered a common species. Its secretive habits could also have contributed to this assumption. It is for these reasons, we believe, that the ferret was not described until 1851. During the next quarter century few specimens were collected for scientific study. Even today probably less than 200 specimens exist in museums.

The reasons for its lack of abundance are not fully known but may be partly an adaptation against overexploitation of its principal food, the prairie dog (Allen 1942). During the century following discovery of the ferret its reported distribution has decreased considerably from its maximum range, as evidenced by the results of a survey for the period 1946 to 1953 (Cahalane 1954). This decline appears to have been caused largely by changing land use and by man's determined efforts to poison the prairie dog. Thus, in areas where prairie dogs have been greatly reduced, the black-footed ferret is either extremely rare or no longer present. For example, 28 of 82 ferrets in the U. S. National Museum were collected in Kansas prior to the early 1900's (D. K. Fortenbery **pers. com.**). By the mid 1950's after intensive prairie dog control (Smith 1967), Hall (1955) considered the ferret to be very rare in that state. The ferret formerly was distributed in northern and central Texas (Seton 1929). In recent years the only reported records are of two specimens from the extreme northwest section in 1953 (Cahalane 1954) and 1963 (M. R. Evans **unpubl. rept.**). Cottam and Caroline (1965) point out that as a result of control, prairie dog populations today are but a small fraction of the numbers in Texas prior to 1915.

FINDINGS

Present Distribution and Status in South Dakota

During the study we gathered 82 records of actual specimens or of what we considered to be reliable sightings of ferrets in South Dakota for the period from August 7, 1964, through 1967. Only animals seen by us or qualified wildlife employees or by others whose reports were closely checked by us for veracity were included. Following is a summary of the records:

10 recovered specimens (mostly killed on roads)
6 sightings of 14 animals by authors
66 sightings of 94 animals by others
—
82 Total

These and subsequent records at the same sites represent 118 different ferrets, although some may have been the same individual at different locations. However an attempt was made to eliminate all duplicate records. Sightings at six of these locations involving 21 ferrets were made by Hillman (1968).

By contrast, records of 143 specimens or reliable sightings of one or more ferrets in South Dakota, altogether totalling 213 individuals, were obtained during the 75 years from the first report in 1889 to August 7, 1964. All the records from 1889 through 1967 are listed on pages 31-36.

In 1967, data based on aerial surveys and reports from district game managers of the South Dakota Department of Game, Fish and Parks

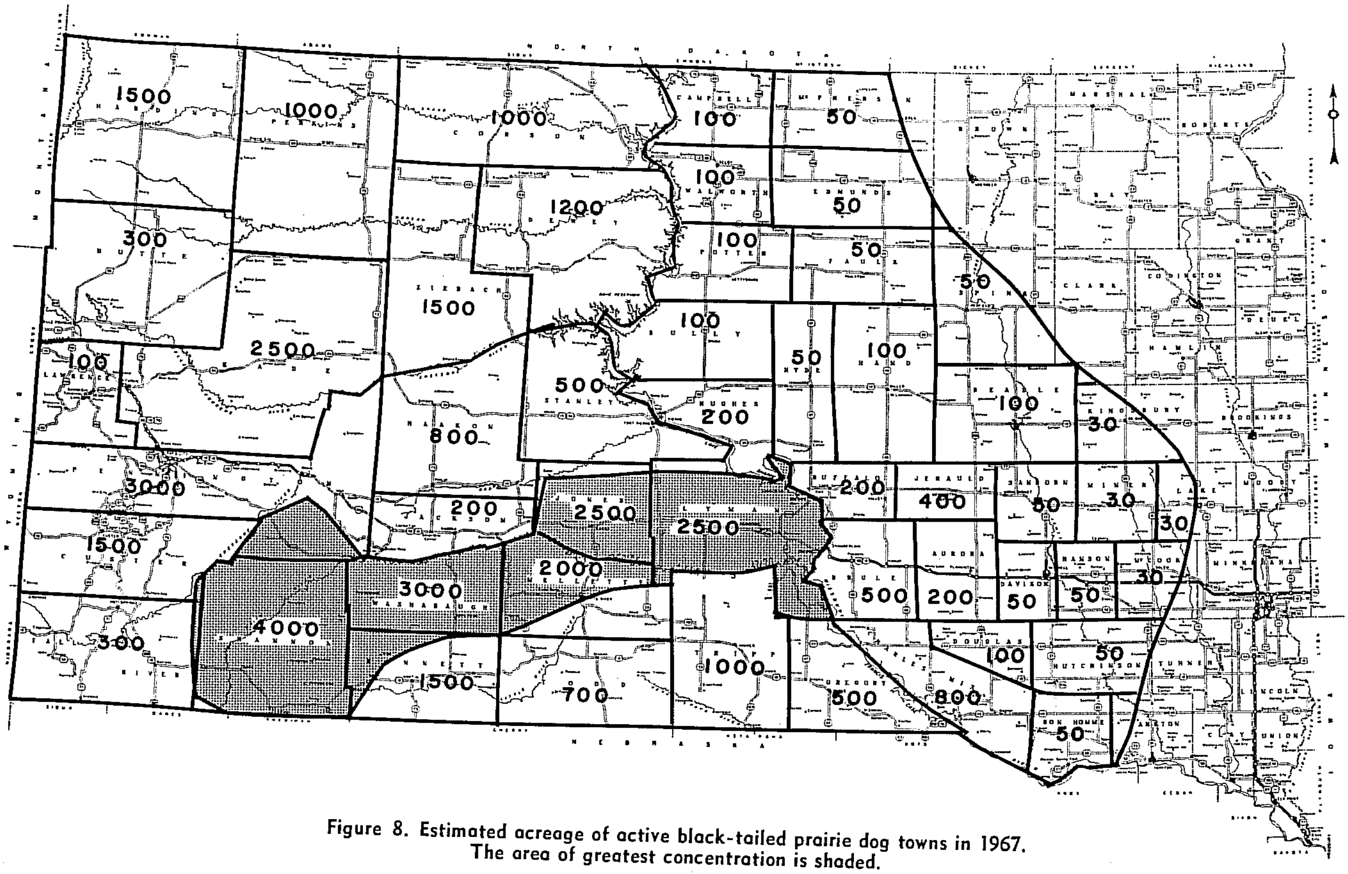

Figure 8. Estimated acreage of active black-tailed prairie dog towns in 1967. The area of greatest concentration is shaded.

showed that about 36,720 acres of black-tailed prairie dog colonies remained in the state. These towns averaged about 20 acres with a few large colonies covering 1,000 acres. The present range of the prairie dog and estimates of acreage by counties are shown in Figure 8. This agrees closely with the distribution shown by Seton (1929) and with an estimate by the Branch of Predator and Rodent Control (now Division of Wildlife Services) of the U. S. Bureau of Sport Fisheries and Wildlife of 32,991 acres of prairie dog colonies in 1961 (Presnall 1963). Very few ferrets were reported from counties east of those bordering the eastern side of the Missouri River and from the southwestern part of the state, areas in which there are few prairie dogs.

Life History

Summer: Family Activities

The black-footed ferrets initially sighted in August 1964 appeared to belong to two families. The animals located at the original site, a 300-acre prairie dog town in Mellette County, were identified as three ¾-grown young and an adult, presumably their mother. The other family, living in a 40-acre town 3 miles north of the original sightings, consisted of a litter of four ¾-grown young and presumably their mother. The following summer on July 13, 1965, another famliy of four nearly half-grown young and presumably their mother was observed on the town of the original sighting. Observations of family activities and photographs of young ferrets presented in this report are of all three families supplemented by observations and photographs of other ferrets from 1966 to 1968.

Additional family groups have been observed in summer. In July 1964, Frank Schramer, Jr., of Martin, South Dakota, told the authors of seeing a family of one adult ferret and four young cross a road at night near a prairie dog town in Washabaugh County. Another family of a female and five ¾-grown young was observed on July 29, 1966, by Conrad Hillman (1968) and Henderson in a Mellette County prairie dog town. Again, on July 10, 1967, Hillman (1968) and Henderson observed a female and four ⅓-grown young in another Mellette County prairie dog town Garst (1954 and **pers. com.**) and Cahalane (1954, Report No. 38) cite a record of an adult with a litter of four full-grown young in Haakon County on July 30, 1953. Cahalane (1954, Report No. 29) also cites a report of a litter of four young in a nest in a haystack in Perkins County in 1952. Lewis Bakken (**unpbl. rept.**) mentioned a female trapped on May 3, 1920, at Broadus, Montana, that was said to have been carrying 10 unborn young. Robert Schilder told us he saw eight ferrets in a Richardson ground squirrel colony in July 1965 in Faulk County. Warren (1942) mentioned nine ferrets having been seen together at one time in Colorado. From these observations it appears that four young are the rule, although litters of three and five or more may occur. The ferret has three pairs of mammary glands (Bailey 1926).

We never saw young in company with two adults, but Cahalane (1954, Report No. 35) cites an observation of two adults and one young together in early July 1953 in Ziebach County. Conversely, during the summer months young ferrets were never observed without being attended by one adult, presumably the mother. A male ferret may remain in the same general area where his young are reared, however. One male was seen near a female and her young in a prairie dog town in Mellette County by Hillman (1968) on August 25, 1966, a few days before the young ferrets left their mother. However, it is certain that the male ferret does not assist the female in rearing the young. The mother alone cared for them and directed their activities until they dispersed. In the early summer the mother was so secretive that, until the young were observed above ground in July, little was learned about their behavior. From her actions it was even difficult to determine which burrow contained the young.

The young rarely appeared during daylight hours. However, adult ferrets would often take advantage of the mid-morning sun's warmth to bask for several hours at a time near the crown of a burrow during the young-rearing period and afterwards in the fall and spring. D. R. Progulske **(per. com.)** noted that a captive ferret lay outside on sunny days, even during the winter.

Each night during the young-rearing period after the sun had set allowing darkness to shield the family's movements, the following drama would usually unfold. Upon digging her way out of her burrow if it had been covered by industrious prairie dogs during the day, the mother ferret would look around with only her head showing. At times she appeared to be sniffing the air. After several minutes she would emerge and cautiously canvass burrows in the immediate area. If she became alarmed, she would run with a rapid bounding gait to the nearest burrow. Often her head would reappear so quickly that it seemed a second animal was present. At times she would stand up on her hind legs, presumably to get a better view or scent (Figure 9). After her safety standard was satisfied, she would proceed to and dig open, if necessary, the burrow containing the young. Immediately thereafter she would enter. Almost always she would remain for 5 to 15 minutes before reappearing at the burrow opening to look about in all directions.

Figure 9. Adult female ferret standing up on hind legs. Mellette County, South Dakota, July 1965. (Adrian)

Gradually she would climb out of the burrow. Once out, she would run quickly from burrow to burrow, sometimes thrusting her head part way into the opening. At other times she entered a prairie dog burrow, quickly reappearing at the entrance, and darted to another burrow. Eventually she would return to the burrow containing the young. After entering she would remain for a short time before slowly emerging.

Finally the young would appear at the opening, first showing only their heads and gradually the foreparts of their bodies (Figure 10). Slowly, one by one, they would emerge from the burrow. If they were reluctant to leave the burrow, as they sometimes were, the mother would seize them individually by the nape and pull each one out (Figure 11). Frequently the mother would have to repeat this procedure several times before a young would remain outside. This shy behavior faded as the offspring grew in age and confidence. Then the mother was able to call the young out by uttering a repeated, low, plaintive **ungh** note.

Even after all the young had emerged from

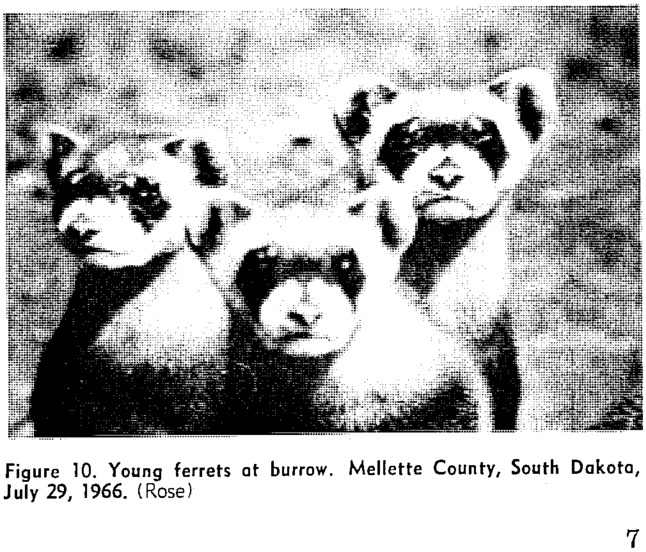

Figure 10. Young ferrets at burrow. Mellette County, South Dakota, July 29, 1966. (Rose)

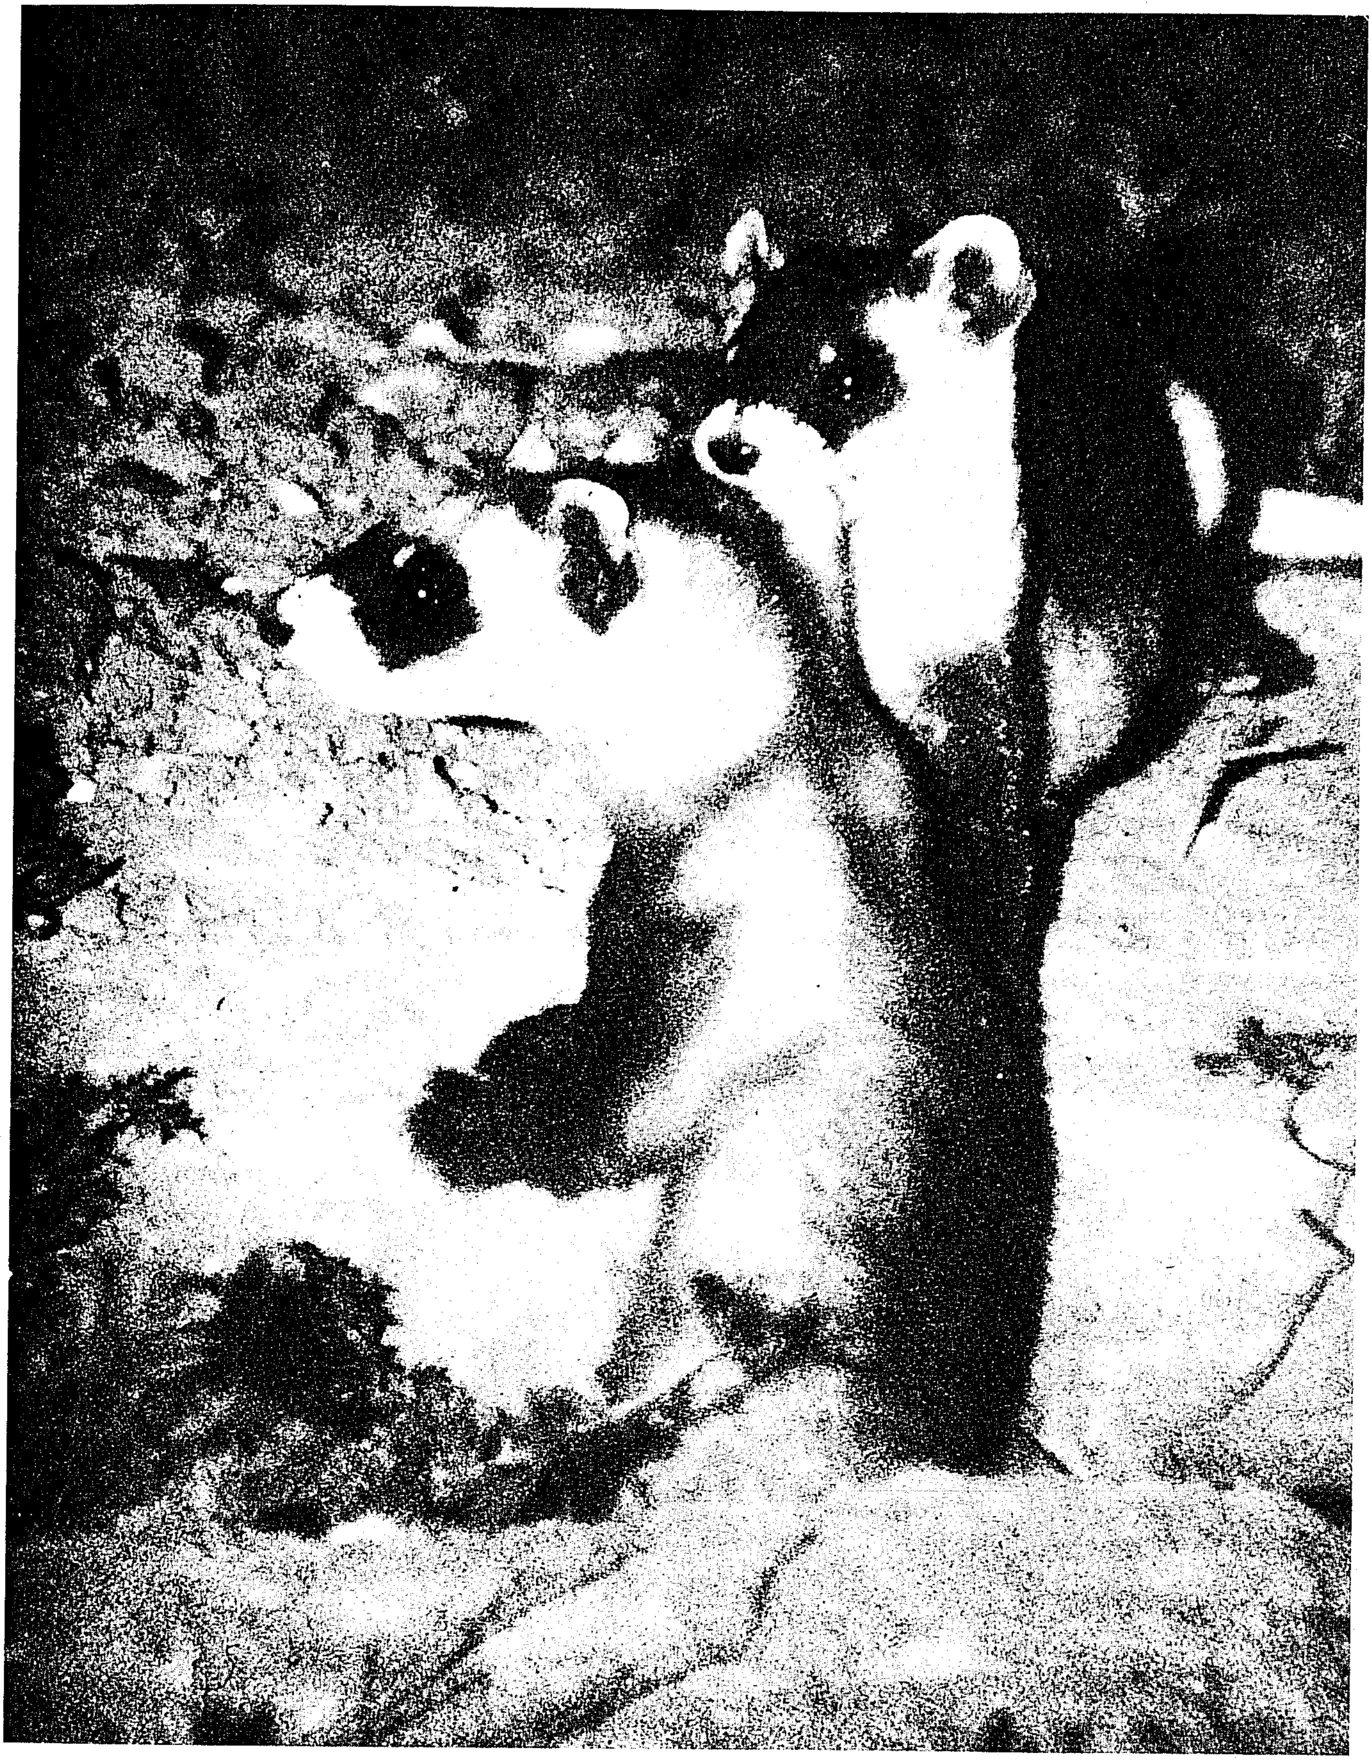

Figure 11. Adult female ferret pulling young from prairie dog burrow by nape. Mellette County, South Dakota, night of July 28, 1966.
(Rose)

the burrow, they hesitated to leave the immediate area. Sometimes they ventured a few feet away from the burrow and quickly darted back. Following the lead of the adult, however, they would eventually move to another burrow in single file with graceful agile bounds, creating the impression of a miniature train. Two of the young in the family observed in 1965 were smaller and more hesitant. However, they would join the mother and the two larger young when they started to move away from the burrow. Arriving at the burrow of the mother's choice, the young would enter after she had checked its safety. Again, she had to coax the reluctant offspring. Both Aldous (1940) and W. E. Garst **(pers. com.)** noted that ferrets they had in captivity were very cautious in new situations. Hillman (1968) observed that a mother ferret carried very young ferrets from one burrow to another.

After relocating her family, the mother again surveyed burrows, entering some, remaining out of sight for a few minutes, reappearing and finally staying down a burrow. Strecker (1910) reports similar behavior.

From June to the middle of July, the ferret family remained in the same general part of the prairie dog town. Around the middle of July, after the young were observed above ground at night, the family extended its area of activity and increased its frequency of relocation. We believe this modification in movement to be a response to both greater activity and food demands of the growing young and local decrease in prairie dogs through ferret predation.

By the middle of July the young ferrets, then nearly one-half adult size, were apparently being weaned as evidenced by an observation on July 16, 1965. When one of the young, having been coaxed out of the burrow by its mother, attempted to nurse, she pushed it away. At this time the mother was noticeably thin and unkempt from the demands of feeding and caring for the young. Her appearance contrasted with the fresh, sleek look of her offspring.

On July 27, 1966, Conrad Hillman (1968) observed an adult ferret, presumably a female, bring up a dead adult prairie dog from one burrow (Figure 12) and drag it to another burrow occupied by young ferrets (Figure 13). This "bringing home the groceries" was observed several times by the authors. Sometimes, however, it may be easier for the mother to lead the young to a below-ground dinner than to drag the food to them at home. For example, on the night of July 10, 1967, Hillman (1968) and Henderson watched an adult female drag three prairie dogs, one at a time, to a burrow. The next night the mother moved the young to this burrow where she had cached the dead prairie dogs. This behavior provides another reason for the increase in family travel after mid July.

Late summer and early fall: Family division and dispersion

By early August the mother ferret was separating the young, putting some in one burrow

Figure 12. Ferret bringing dead prairie dog out of burrow.

Figure 13. Adult female ferret with kill of adult prairie dog. Mellette County, South Dakota, July 28, 1966. (Rose)

and others in another. It was at this time that some of the young were first observed hunting occasionally at night by themselves. By mid-August they were seen during daylight hours, peering out of burrows, playing near the entrance and sometimes following their mother. The young ferrets were achieving their independence; they had advanced from shy, timid creatures to confident and inquisitive adolescents. The curiosity of both young and adult ferrets was displayed on several occasions when we successfully called animals from their burrows by imitating the coaxing sound made by the mother or by using a predator call to simulate the distress note of a rabbit. The young were still cautious, however, and would quickly retreat underground if the sound was too loud and harsh. Playing a recording of the alarm chatter (described later) of a captive individual evoked only mild interest from animals in the wild.

By late August or early September, when the young was as large as the adult, the ferret family started to disperse and was no longer seen as a closely knit group. However, on October 6, 1965, three animals were seen in close proximity on the 300 acre "south" town by Adrian and Springer.

Additional evidence suggests that the period from late summer through early fall is the principal time of dispersal. Altogether 43 per cent of the 70 ferrets found dead along roads or seen by casual observers outside of prairie dog towns were noted between mid August and mid October. Five specimens, (Pages 33-36, records 96, 107, 110, 204 and 224) could be aged and sexed. They consisted of three young males, one young female and one adult male. Age was determined by body weight and size, condition of gonads, conformation of baculum as noted in mink (Elder 1951) and amount of tooth wear.

In spite of fall dispersal a few animals inhabited the prairie dog towns under study as long as these sites remained suitable. Since ferrets were not marked for fear of disturbing them, the age and sex of these animals was not determined. The "south" town was inhabited by ferrets for at least 3½ years until the winter of 1966-67.

Some data show that ferrets will visit formerly used sites. In May 1965 Adrian excavated one burrow which the ferrets under observation in the 40-acre "north" town were known to have inhabited consistently during August 1964. The burrow angled downward at about 60° from horizontal for about 2 feet and then went straight down for 8 feet before leveling off horizontally. After excavation was terminated, the excavation was not filled in. Instead, boards were laid across at ground level to prevent cattle from falling into the opening. During the early morning of April 21, 1966, a ranch employee reported seeing a ferret enter the opening under the boards. On April 23, 1966, we inspected the burrow and found that a paper plug placed by Adrian in the burrow opening at the bottom of the 12-foot hole the previous year had been dug out by an animal. We supposed from the direction of the burrow that the remaining unexcavated portion led to another opening at ground level about 30 feet away. No further evidence of ferret activity was noted at the excavated burrow. Instances of ferrets visiting abandoned prairie dog towns have been reported by other investigators.

Late fall, winter, and spring: Sedentary existence and breeding

Observations of ferrets and their tracks showed that the animals were usually found singly during the late fall, winter and early spring, indicating that the young had achieved their independence. When two or more ferrets were observed to be active in the same prairie dog town during this period, they did not appear to associate with each other. At this time of year ferrets use a number of dens and may or may not favor certain ones.

As during the summer, activity was largely nocturnal, although more diurnal activity was noted in fall and spring than at other times of the year. Dartt (1879), W. E. Garst (**pers. com.**) and D. R. Progulske (**unpubl. MS.**) all noted that captive ferrets were most active at night.

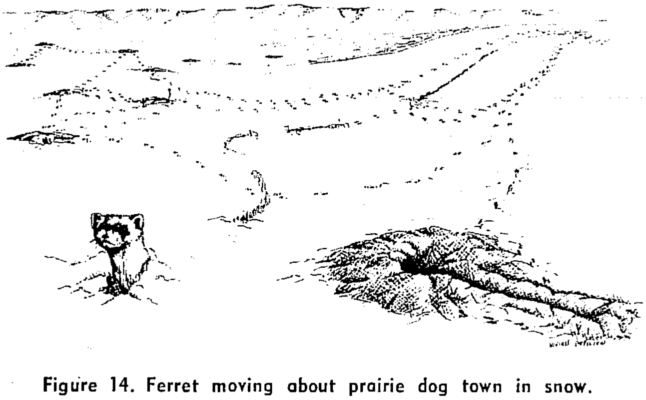

Figure 14. Ferret moving about prairie dog town in snow.

Tracking in the snow (Figure 14) showed that ferrets remained active through the winter, even when the outside temperature was as low as -18°F. A captive ferret did not hibernate but ventured out during sub-zero weather (D. R. Progulske **pers. com.**). Young (1946) states that the "ferret lays up throughout parts of the winter in some abandoned prairie-dog hole, or one it has appropriated to itself, until the weather moderates above ground."

The exact time of mating in black-footed ferrets in South Dakota is not known. By backdating from the estimated age of the young when first observed and using the 42-day gestation period of the closely related domestic fitch ferret (Bissonnette 1938), it is believed to be in April or May. Birth would be in May or June. An adult female ferret killed by a motor vehicle in Jones County on May 16, 1967, appeared to be in heat. Another female trapped May 3, 1920, at Broadus, Montana, was said to be carrying unborn young (Lewis Bakken, **unpubl. rept.**). A nursing female was collected on June 20, 1913, at Quinion, North Dakota (Bailey 1926), and young ferrets were reported in June in Billings County, North Dakota (Cahalane 1954, Report No. 22). A litter of ⅓-grown young ferrets observed by Hillman (1968 and **pers. com.**) on July 6, 1967 had their eyes only partially open. A ferret captured in Lyman County in August 1961 was thought to be less than 3 months old (D. R. Progulske **unpubl. MS.**).

Characteristics and Behavior

While engaged in family activities and later after achieving indepedence, the ferret exhibits the general characteristics and behavior patterns associated with typical life processes and features which constitute special adaptations of the species.

Senses:

The relatively large ears of the ferret (see Figure 15) suggest that its hearing is well developed. On one occasion Adrian tested the hearing ability of young ferrets. While observing them from a distance of about 5 feet, he scraped his foot across the floor of the truck. The young reacted almost instantaneously and ran down their burrow. On another occasion as a mother and young were being watched at night with a

Figure 15. Young ferret showing large eyes and ears. Mellette County, South Dakota, July 29, 1966. (Henderson)

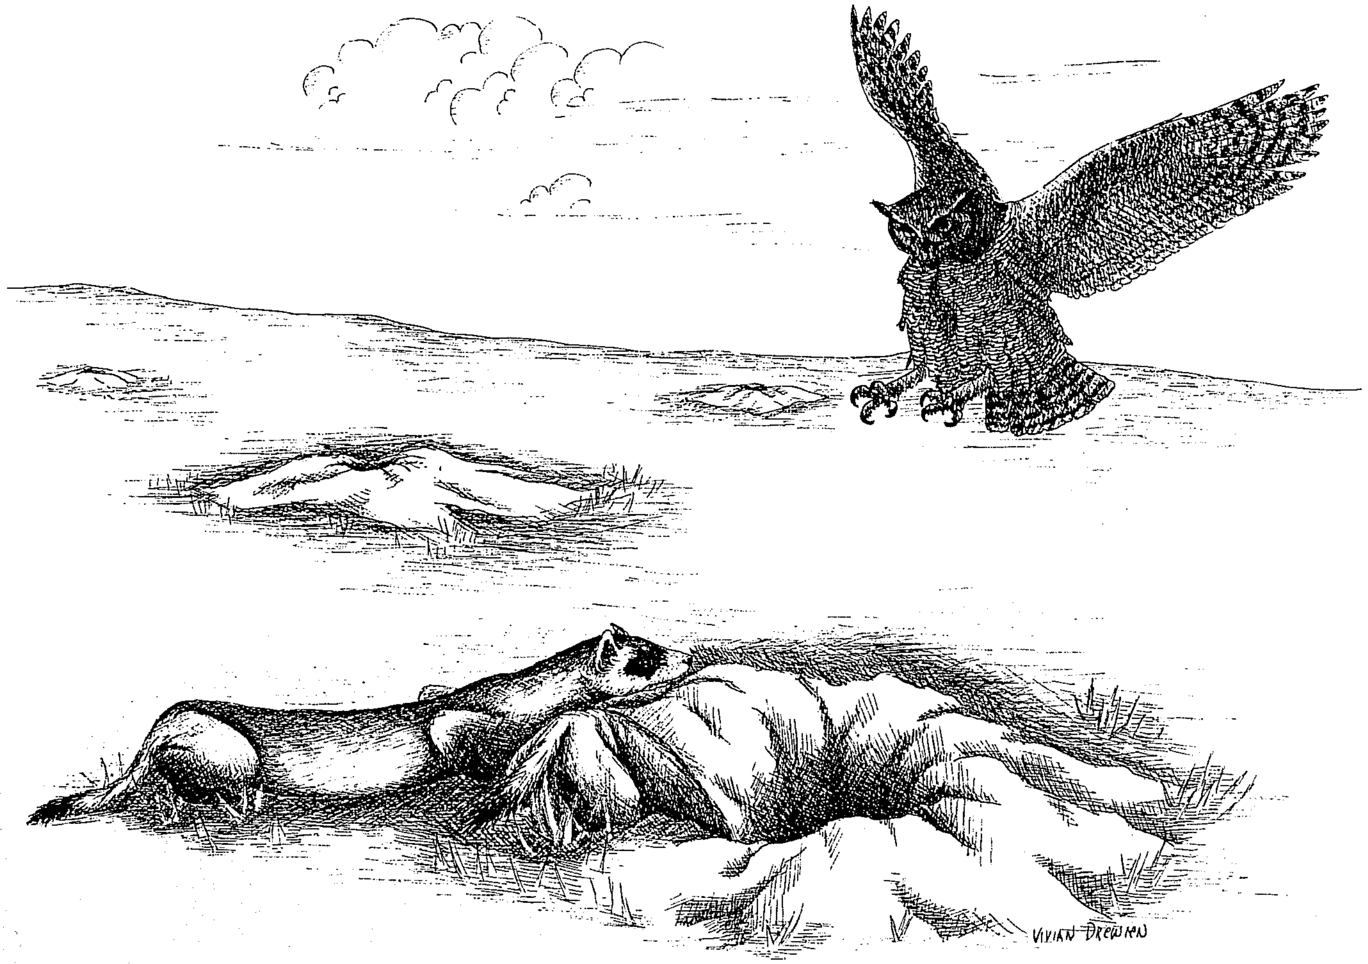

Figure 16. Great horned owl swooping on ferret.

light, they suddenly ran down their burrow about 7 feet away. Several seconds later a great horned owl swooped over the burrow entrance (Figure 16). It is believed the ferrets heard the owl. Twenty minutes later the young were playing above the ground again.

Smell also appears to be an important sense. Frequently the mother ferret would point her nose upward, apparently sniffing the air. Ferrets also seemed to rely on their sense of smell when nosing about burrow openings and when detecting dead prey put beside their burrows.

Sight is relied upon at close range but does not seem to be as important at distances over 300 feet. The ferret must be well adapated to seeing in poor light as they are active on dark nights when the moon is new.

Water requirements:

Ferrets were never seen drinking water, even though a creek and a few stock ponds and intermittently wet ponds were available on or near the several study areas. Water may be obtainable at the bottom of some prairie dog burrows. Proof that a black-footed ferret will drink water on occasion is provided by D. R. Progulske (**unpubl. MS.**) who observed that an animal he held captive drank water irregularly.

Fecal and urinary habits:

Only a few scats (fecal pellets) thought to have been deposited by ferrets were found. On October 14, 1964, Adrian observed a ferret drop the scat shown in Figure 17. It is suspected that ferrets deposit scats underground in a manner characteristic of weasels (Murie 1954). Presumed ferret scats collected from the surface of the ground had been deposited separately, usually near the burrow mound.

Ferrets urinate above ground at least some of the time. Urination sites at the opening of burrows were readily noticeable in the snow when

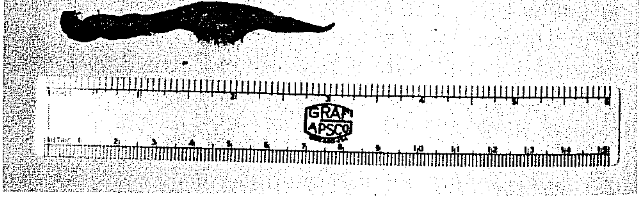

Figure 17. Scat dropped by a black-footed ferret. Mellette County, South Dakota, October 14, 1964. (Henderson)

ferret tracks were followed in the period from late December through March.

Aldous (1940), D. R. Progulske **(unpubl. MS.)** and W. E. Garst **(pers. com.)** noted that the ferrets they held in captivity made fecal and urinary deposits in one corner of their cages or sometimes in their den boxes. Garst's animal usually threw sand over the waste and sometimes dug a hole.

On the night of January 18, 1965, a stuffed ferret was placed at the entrance of a burrow which a ferret had entered. A few minutes later this ferret (sex unknown but believed to be a male) came out and investigated the stuffed ferret. Our subsequent examination showed that it had urinated on the board on which the stuffed ferret was mounted.

Odor:

Although we did not handle any live ferrets, we noted only a mild odor resembling that of a mink when we were in close proximity to disturbed individuals or when we examined dead animals. Hoffmeister (1963) states that the ferret has poorly developed scent glands, and Ralph Block **(unpubl. rept.)** did not note any odor. However, W. E. Garst **(pers. com.)** found that captive individuals he studied had an odor similar to that of a wet dog. This became more potent when the animals were disturbed. George Barnes **(unpubl. rept.)** observed that ferrets when aroused have a very disagreeable odor closely resembling that of a mink.

Play:

As do some other mammals, ferrets exhibited definite signs of play. Scuffling noises heard at burrow entrances during mid-July attested to the fact that the young were active and probably tussling inside their burrows. Above-ground observation confirmed their playful nature. On August 18, 1964, at 4:25 a.m., Adrian was watching two youngsters outside their burrow when one leaped up and executed a mid-air somersault. He also recored in his journal:

> "The two ferrets . . . seem to be playing. The ferrets can hop backward very fast. One just nipped the other one on the ear. . . . Both ferrets are playing; one stands still while the other jumps around. Then the first jumps at the second."

At times young ferrets appeared to be walking on their tiptoes. They also arched their back and tail and danced about. Aldous (1940) noted that a young captive ferret he raised liked to sneak up and grab a person's cuff or heel.

This playful spirit is not lost in the process of reaching maturity. During the winter Adrian found evidence of a slide in the snow made by a ferret (Figure 18). This individual had obviously

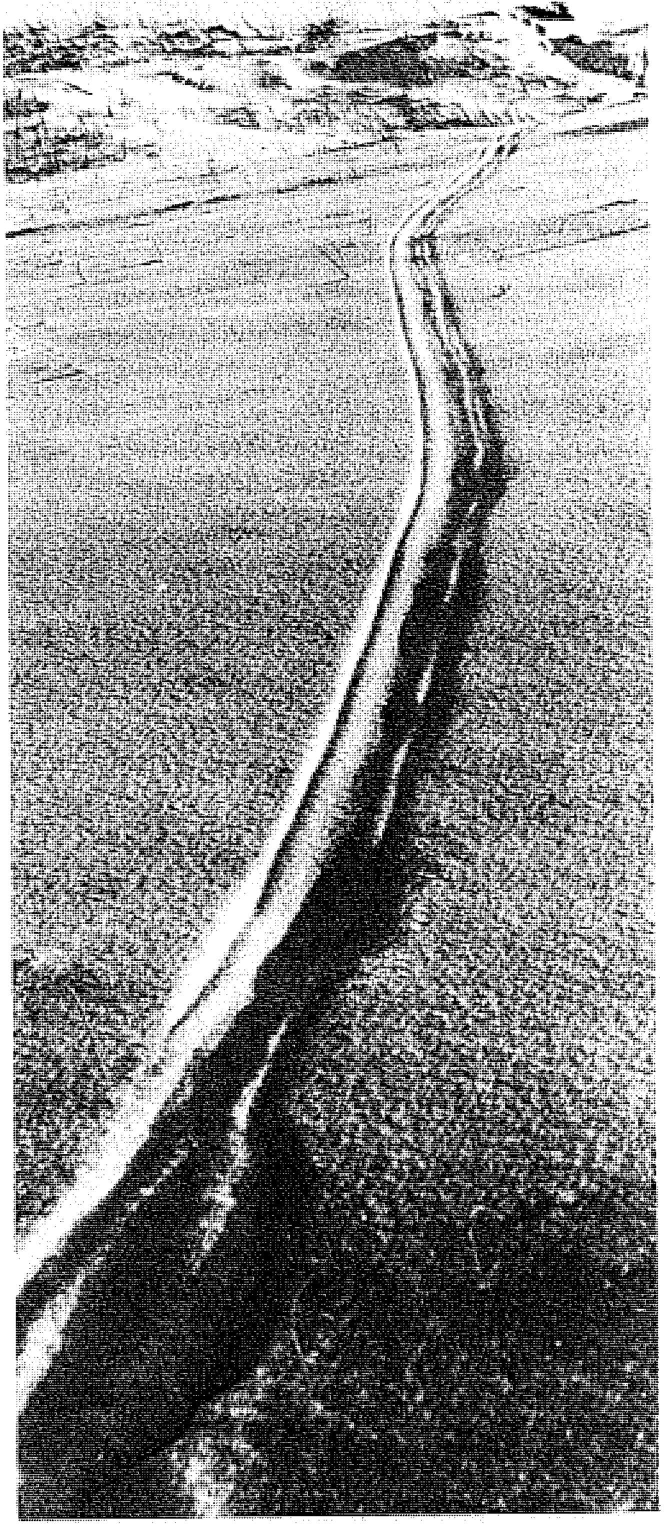

Figure 18. Ferret slide marks in snow on hill. Mellette County, South Dakota, January 1965. (Adrian)

Figure 19. Ferret signs: Tracks, front (above left) and hind (below left), and made when bounding (center); scats (right).

slid down the snow-covered hillside on its belly in much the same manner that a river otter slides down stream banks. Mink also have been found to slide down snow-covered slopes (Seton 1929, Marshall 1935). Ferrets tunnel under and through snow as do weasels (Seton 1929, Murie 1954). Adrian described this phenomenon in his journal on December 26, 1964:

> "At one part of the town where ferrets have been active, there was sign indicating where one animal had gone under the snow for about 6 feet before poking its head up and then continuing to tunnel through the snow." (Figure 14).

Tracks:

The hardness of the soil in western South Dakota prairie dog towns makes it difficult to find tracks left by ferrets. Therefore, most of the ferret tracks (Figure 19) were observed when snow covered the ground (Figure 14). Usually the distance between tracks in the normal bounding gait was 12 to 16 inches. One animal which was tracked in the snow appeared to have jumped 6 to 8 feet at times. Seton (1929) noted that the short-tailed weasel has been known to jump similar distances.

Identifying ferret tracks in fresh snow is complicated by their possible confusion with mink tracks, which are similar. On several occasions mink (Figure 4) were observed in the "south" prairie dog town in Mellette County, moving about in much the same manner as a ferret. At 10:30 a.m. on February 5, 1965, Adrian saw a mink going from burrow to burrow. Again on April 10, 1965, at 1:00 p.m. he wrote:

> "I saw a large mink in the central part of the town along the creek. It would make three or four bounds, stop, look around, and bound again. Soon it disappeared over the creek bank."

On April 22, 1965, at 7:30 a.m., Springer and Adrian checked the prairie dog town with binoculars and found many prairie dogs above ground. Adrian recorded:

> "Some were grazing; others were building up their burrows. In the north central part of the town, we saw several prairie dogs sitting stiffly and apparently alarmed. Investigation revealed a mink in the town. It was going in and out of burrows and apparently did not see us . . . Its paws and lower part of its body were wet from entering a small

Figure 20. Adult female ferret dragging dirt out of burrow. Mellette County, South Dakota July 28, 1966. (Rose)

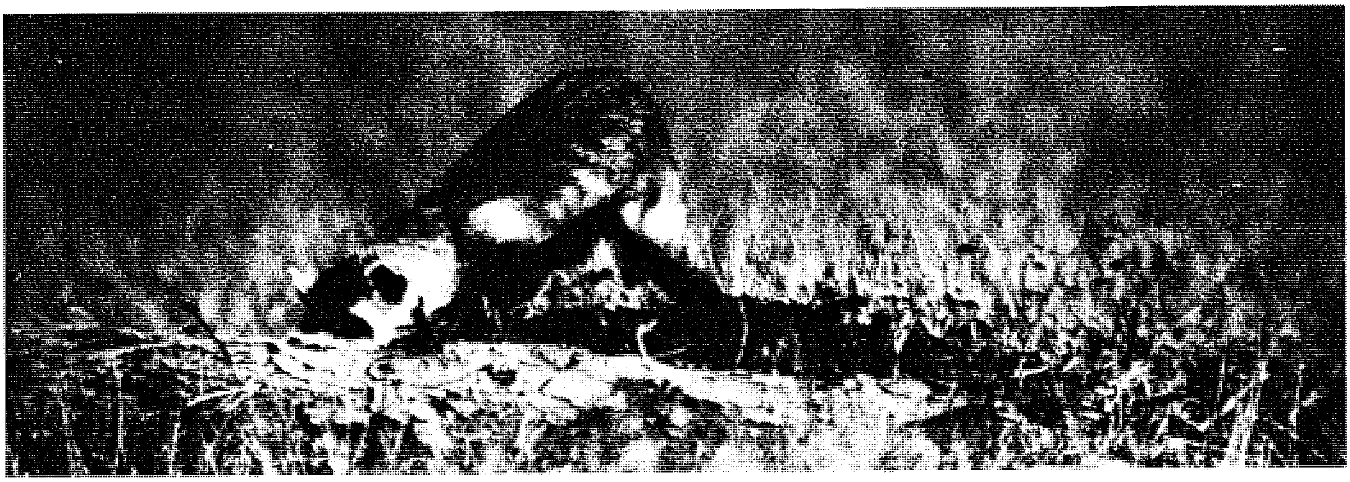

Figure 21. Ferret kicking dirt backwards after backing out of burrow in same path as on previous trips. Mellette County, South Dakota, July 28, 1966. (Rose)

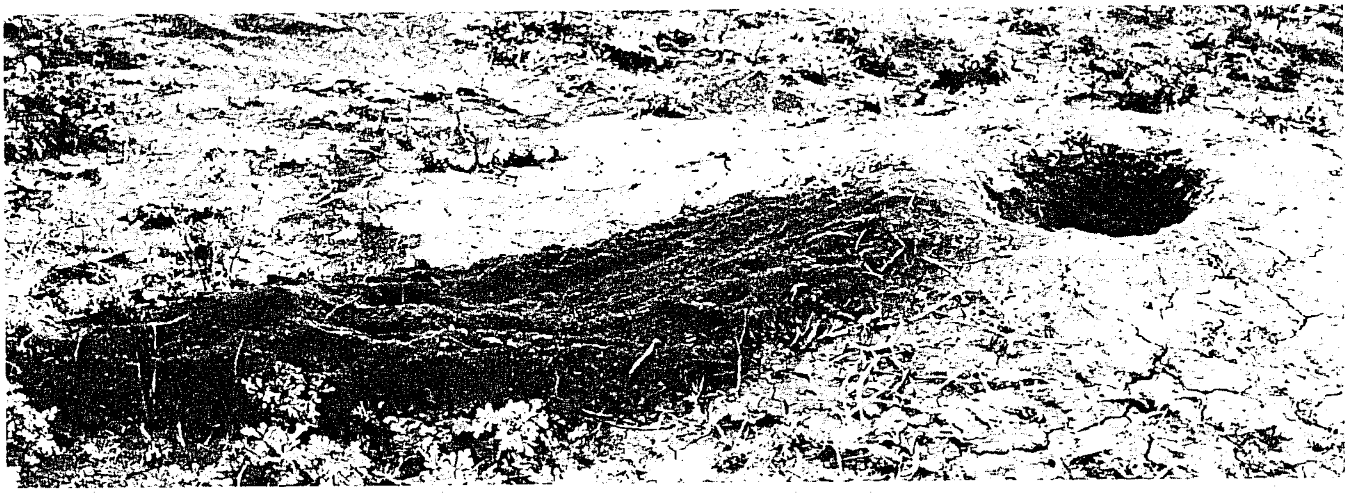

Figure 22. Characteristic trench made by ferret digging dirt out of prairie dog burrow. Mellette County, South Dakota, July 28, 1966. (Rose)

temporary pond. The mink then spotted us, but with the wind blowing toward us it was unable to determine what we were. It went hesitantly from burrow to burrow and when it had worked its way downwind, our scent reached it and it ran away to a prairie dog burrow about 200 feet away. It went down the burrow, came up and looked at us and went down again. Although we watched the burrow at a distance for about 15 minutes, it did not come out."

The mink and the ferret belong to the same genus; they are nearly the same size and to the human observer their tracks and scats are almost identical (Murie 1954). If mink are feeding on prairie dogs, their droppings probably would be similar to those of a ferret. It appears that where streams, stock ponds or other water areas are present nearby, mink are more frequent visitors to prairie dog towns than is generally realized. For this reason the possibility of the presence of mink should not be overlooked.

Digging:

As would be expected in an animal that spends much of its life underground in burrows, the ferret has well developed claws on its front feet — an adaptation for digging. When excavating in a burrow the ferret backs out with the dirt held against its chest with its front paws (Figures 20 and 21.) It generally comes out of the burrow on the same side. In each subsequent trip the animal drags the load of dirt a little further from the entrance, sometimes kicking it backwards. After repeated trips a trench from 3 to 5 inches wide and from 1 to 9 feet long is formed (Figures 22 to 24). Sometimes when only a small amount of dirt is removed, a trench is not formed. We noted that ferrets constructed trenches most often at night. A ferret observed by Springer and Adrian on the night of July 23, 1965, carried up a load of dirt about every 15 seconds. W. E. Garst **(pers. com.)** found that a captive ferret constructed a trench in cleaning out a burrow.

We consider trenching to be diagnostic of ferrets. No other animal we observed in a prairie dog town left a structure of this shape and size. The black-tailed prairie dog will excavate earth but generally this is deposited all around the burrow entrance to form a mound. Later it will build the mound higher by adding dirt from outside the mound. This direction of movement is just opposite that made by a ferret. In the spring of 1965 Floyd Vogelgesang told the senior author he saw a long-tailed weasel near a stock pond in Washabaugh County dig a trench similar to that of a ferret. However, the dimensions were 2 inches wide by 12 inches long. Mink on prairie dog towns have not been observed to dig.

White-tailed prairie dogs do not occur in South Dakota. Limited observation by the auth-

Figure 23. Good example of ferret trench. The observers are Richard Adrian (left) and Bill Pullins. Mellette County, South Dakota, January 20, 1965. (Kittams)

Figure 24. Old ferret trench as found after snow has melted and before weather warms. Prairie dog activity would erase this trench. Mellette County, South Dakota, March 1966. (Henderson)

ors of this species in Wyoming and Arizona indicates that the burrows are dug on more sloping ground than that occupied by black-tailed prairie dogs and that they tend to throw dirt out on the downhill side. This dirt is deposited in a broader but often shorter area than that by a ferret. No trenches suspected of being constructed by ferrets were observed in these white-tailed prairie dog towns.

Why the ferret digs at some burrows and not at others is not known. Since it commonly lives in prairie dog towns, it appears that the ferret ordinarily does not dig its own complete burrow system but instead appropriates that of a prairie dog, perhaps making some modification. Sometimes it digs to remove dirt thrown by prairie dogs down a burrow presently or recently occupied by a ferret, as described in the section on "Relationship to black-tailed prairie dog." At other times it probably digs to remove plugs of earth that prairie dogs construct inside their burrows to seal them off from the outside. R. R. Lechleitner **(pers. com.)** indicates the black-tailed prairie dog commonly plugs its burrow when it retires for the night or for extended periods.

We noted apparently more trenches in prairie dog towns in winter than in other seasons and relatively more in towns with a small prairie dog population than in those with large numbers of prairie dogs. Trenches probably are more evident in winter because at that time prairie dogs are less active, especially on non-sunny days. Thus, they do not erase the sign as quickly as they do during more active periods. Also, if the soil in the trench freezes, it cannot be easily disturbed by prairie dogs.

The repeated contact by a ferret dragging its long body at the crest of a burrow mound usually forms a smooth place (Figure 25). This characteristic was noted also by Garst **(pers. com.)**.

Another indication of ferret activity may be associated with its digging habits. In removing loose dirt from a burrow, the ferret may bring up hard dirt balls like those shown in Figure 26. These balls are formed of concentric layers of clay soil on which most prairie dog towns in western South Dakota are established. Commonly called Fort Pierre clay soil and locally referred to as "hard pan," this soil is normally more than 50 per cent clay. It is from a few inches to several feet in depth and usually on a layer of shale. The presence of dirt balls does not positively indicate ferret presence since they are found at a few burrows in nearly every prairie dog town sometime in the year. The balls, however, seem to vary more in size and in shape when located at

Figure 25. Ferret trench showing worn place near burrow crown. Mellette County, South Dakota, February 1966. (Henderson)

Figure 26. Dirt balls at burrow entrance. The nickel shows comparative size. Mellette County, South Dakota, July 23, 1965. (Springer)

ferret burrows then when found at prairie dog burrows. Although dirt balls are more frequent in wet weather, a few are present in dry periods at burrows that a ferret has chosen to frequent. Even though more investigation is needed to prove whether prairie dogs form most or all dirt balls, the occurrence of these structures at many ferret burrows makes them a potentially useful ferret indicator.

Ecological Relationships

Relationship to black-tailed prairie dog:

Dependence upon prairie dog. In a consideration of the intermammalian relationship of the black-footed ferret in South Dakota, the black-tailed prairie dog is a most important species. All indications vitally link the two animals.

The prairie dog's burrow provides a more moderate environment for the ferret when outside temperatures are high or low and during inclement weather. In one instance in June when the outside temperature was 128F. in the sun and 80 F. in the shade, it was only 53 F. at a depth of 8 feet in a prairie dog burrow. Wilcomb (1954) found the following temperatures during July and August: soil surface, 75 to 119 F.; air 6 feet above ground in shade, 73 to 90 F.; and air 41 to 49 inches below ground in a prairie dog burrow, 78 to 83 F. During January and February he recorded the following temperatures: soil surface, 24 to 66 F.; 6-foot elevation, 15 to 55 F.; and burrow at depth of 42 to 66 inches, 40 to 51 F.

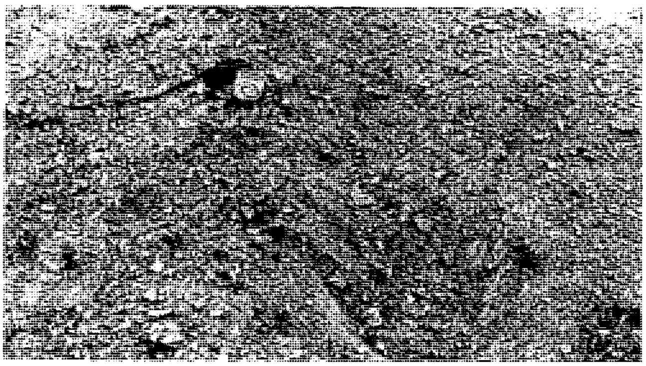

Figure 27. Ferret burrow covered by prairie dogs. Mellette County, South Dakota, October 1964. (Adrian)

There also seems to be little doubt that the prairie dog is the ferret's main food. This predator-prey relationship accounts for the ferret's titles of "prairie dog hunter" (Coues 1877), "prairie dog ferret" (Lantz 1905) or "king of the prairie dogs" (Vetal Romero **pers. com.**). Ferrets will consume items other than prairie dogs (see section on "Alternate sources of food") and have been observed away from prairie dog towns. However, they are most commonly seen in such towns, which suggests that these are their principal abode.

Examination of one known ferret dropping collected in a prairie dog town in Mellette County by Adrian as well as two droppings collected by Hillman (1968) showed that they consisted entirely of black-tailed prairie dog hair and bones. Prairie dogs were the predominant potential prey available to the ferrets. A prairie dog was found in the stomach of a ferret taken in Colorado (Coues 1877). The stomach of another ferret trapped in Pennington County in the summer of 1952 had only a grass seed which probably was taken incidentally (S. P. Young **unpubl. rept.**).

The 40-acre "north" town had about 167 active prairie dog burrows when the female ferret and four young were discovered in August 1964. By December 1964 only four active prairie dog burrows remained. This decline continued until the prairie dogs had completely disappeared by the spring of 1965. In the spring of 1966 many thirteen-lined ground squirrels, a species which previously had been uncommon in the town, were observed using the abandoned prairie dog burrows as well as their own burrows.

The 300-acre "south" town experienced a similar decline from approximately 1200 active burrows in the fall of 1964 to only about 20 in the spring of 1966. No prairie dogs remained in the spring of 1967.

Plague, a disease transmitted by fleas, is known to decimate prairie dogs at times. Prairie dog fleas were collected from several animals in the small town during the fall of 1965 and submitted to the Plague Laboratory, Communicable Disease Center, San Francisco, California. These fleas were reported not to be carrying plague bacilli. The possibility of other disease was not investigated, but there was no above-ground evidence of mortality induced by pathogens.

Investigation of a number of other towns in Mellette County disclosed that prairie dogs had disappeared in four of them without having been poisoned by man. Ferret sign, mostly old and consisting of trenches, was present in all four. These plus the "north" and "south" towns all occurred in a 3 x 6 mile area. Five other towns in this same area did not decrease in size during this period and repeated investigation showed an absence of ferret sign.

Thus, from the evidence collected, it appears that ferrets, and other predators, may assist in the depopulation of some prairie dog towns. A number of old reports exist in which ferrets are said to have greatly diminished or exterminated prairie dogs in a town (Roosevelt 1900, Lantz 1905, McCandless 1908, J. W. Glessner **unpubl. rept.**, A. E. Oman **unpubl. rept.**, S. W. Glenn **unpubl. rept.**, S. P. Young **unpubl. rept.**).

It is noteworthy that when a ferret is active on a prairie dog town during the day the prairie dogs remain above ground. In spite of all the time spent in observing ferret behavior, a ferret has been witnessed actually killing a prairie dog above ground only once (Hillman 1968). Apparently, prairie dogs are more secure from ferrets here than in their burrows. Conversely, when larger predators, such as a badger, coyote, or man, that cannot readily pursue prairie dogs down their burrows, appear on a town, the prairie dogs seek refuge below ground. From this we conclude that the major portion of actual killing of prairie dogs by ferrets occurs underground, probably at night when prairie dogs have retired to their burrows and ferrets are active. An exception to nighttime feeding may be during the day when adult prairie dogs are on the surface and when young prairie dogs that are in their burrows are easy prey for ferrets.

Springer did find a dead prairie dog, its throat cut, at the crown of a burrow on the night of October 6, 1964, in the 300-acre "south" town in Mellette County. When he came on the town after dark at 7:15 p.m., he noted a ferret. As he approached, it moved off and circled part of the town, returning to the original site. At this time Springer first noted the dead prairie dog. When he approached the ferret again, it partly descended the burrow. While Springer was taking pictures, it seized the prairie dog and dragged it into the burrow. Then it proceeded to consume it for 30 minutes in a chamber about 4 feet under ground. Springer could see part of the ferret and hear it eating. Afterwards it came out of the burrow and descended into another one. Eleven hours later Springer and Adrian dug out the burrow but found no trace of the prairie dog. The burrow ended in the chamber, although examination showed that a tunnel leading further down had been blocked off some time previously.

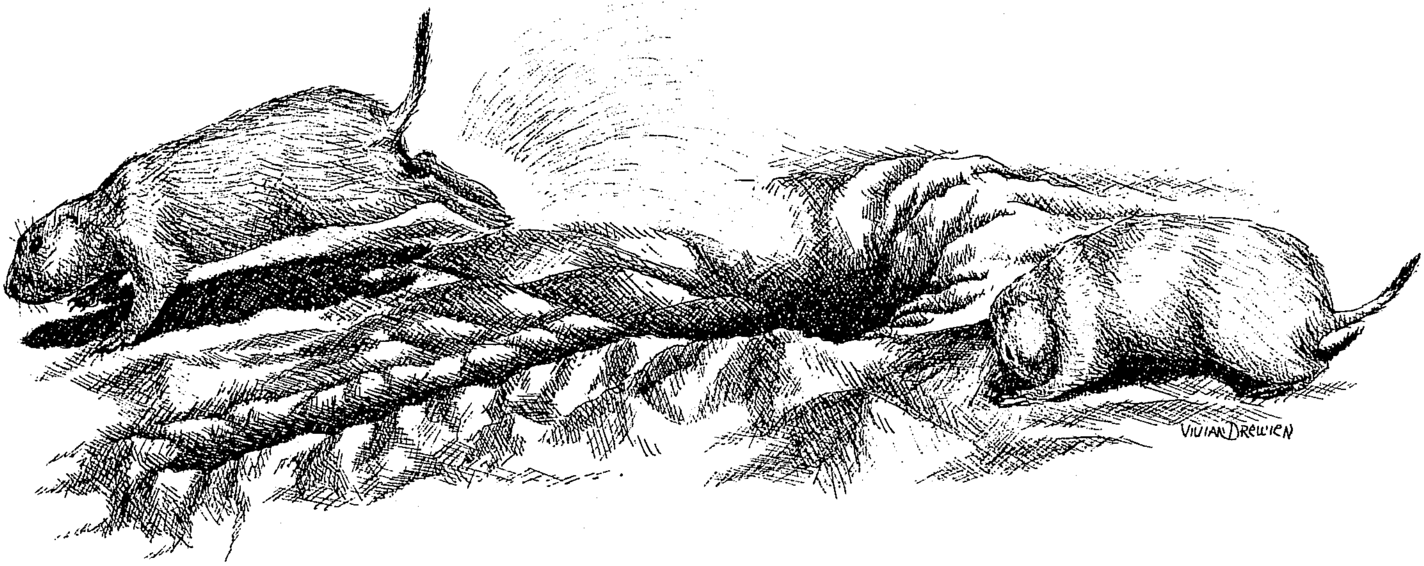

Figure 28. Prairie dogs covering burrow occupied by a ferret.

A recently killed prairie dog, again with its throat cut, was reported to Adrian by Clarence Krogman on March 3, 1965. It was at the entrance to a burrow in a prairie dog town in Mellette County that was being poisoned with strychnine-coated oats. Two days later Adrian observed ferret tracks and dirt trenches in the snow. Lantz (1905) mentions that an occasional dead prairie dog with its throat cut is found outside a burrow.

It seems likely in the above instances that the ferret either chased the prairie dogs up to the surface where it dispatched them or killed them underground and brought them up to the surface.

In December 1964, Adrian found many ferret tracks at the snow-covered 300-acre "south" study location. Near one burrow which had been recently dug out by a ferret, he found a black-

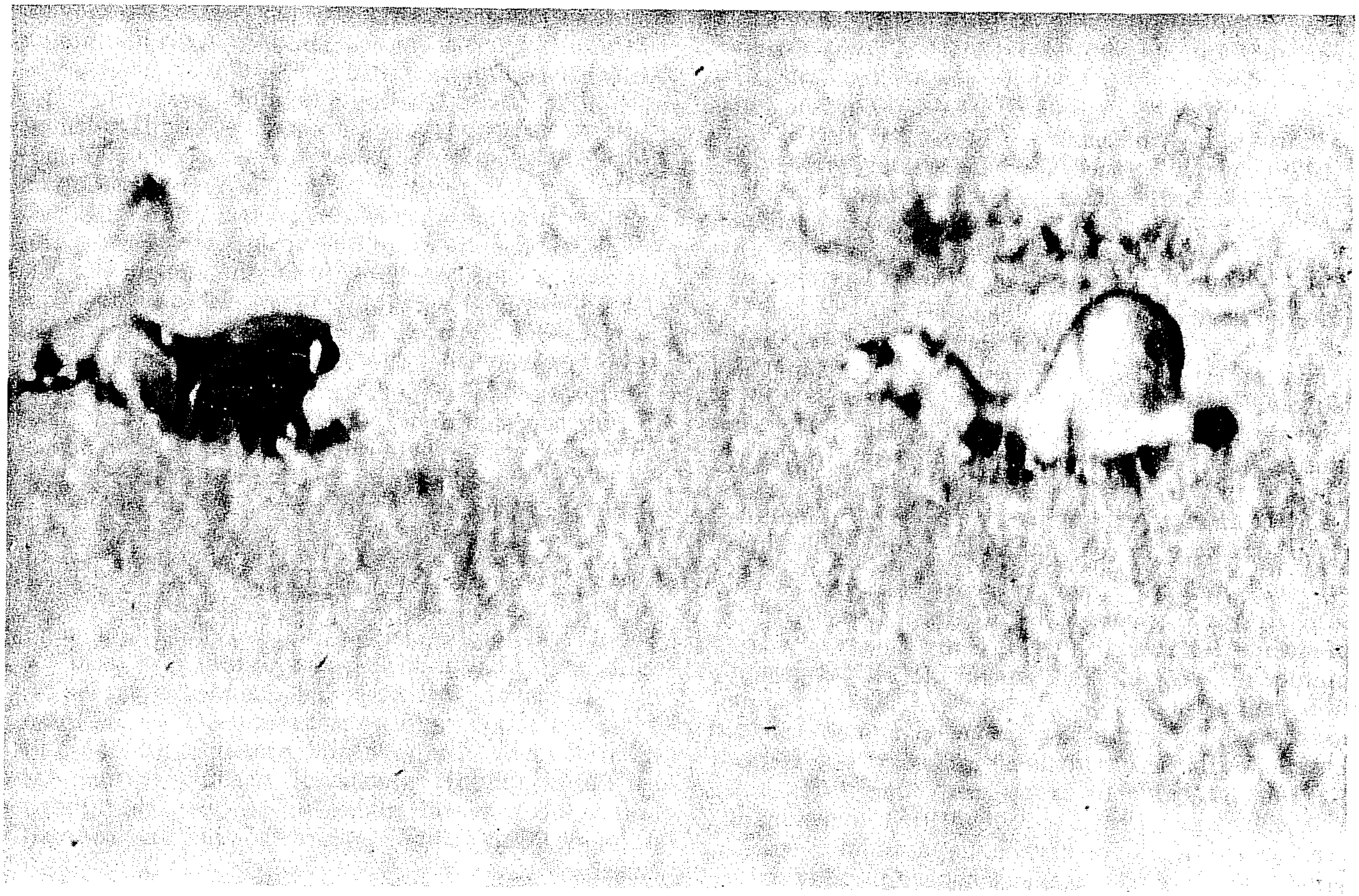

Figure 29. Black-tailed prairie dog running in front of black-footed ferret. Mellette County, South Dakota, August 1964. (Rose)

proached that burrow and made darting movements toward the ferret from about 2 feet. Whenever the ferret backed down the burrow, the prairie dog dug furiously in an effort to cover the burrow opening. Subsequently, the ferret ran to a nearby burrow and descended it.

On a number of other occasions prairie dogs were seen running in front of a ferret as if to divert it or confuse it (Figure 29). Although prairie dogs will intimidate a ferret and sometimes cause it to return to its burrow, close observation showed that the prairie dogs would usually give way to a ferret if it persisted in its course of action. Prairie dogs closely followed a ferret moving about a town and seemed to be chasing it but always fell back when the ferret turned and faced or chased them. Mead (1885) recorded similar observations. At times it appeared that a ferret would retreat in order to lure the prairie dogs to a point where the ferret would chase one of them. In the few instances where a ferret was forced to withdraw, it was believed to be a younger, less experienced animal.

At times a ferret may be injured by a prairie dog. In August 1965 the mother ferret on the "south" town incurred a large cut that ran from her forehead down between her eyes. She did not have this cut when observed previously. The injury, however, did not seem to interfere with her vision or to be infected. However, she often scratched the scab with her hind paw. Possibly this wound was inflicted in an encounter with a prairie dog or one of the animals described in the section on enemies. D. R. Progulske **(unpubl. MS.)** witnessed a fight in which a prairie dog bit a captive ferret on the side of the face and shoulder before the ferret killed it.

Although prairie dogs ordinarily cannot kill a ferret they will if the situation permits. Support for this statement is based upon a report of a ferret caught in a trap in Kansas. This animal was attacked and killed by a small group of prairie dogs. (Kellogg 1960).

Relationship to other animals:

Alternate sources of food. The fact that black-footed ferrets have been found living in haystacks and alfalfa fields, around buildings and in proximity to other animals besides prairie dogs indicates that they can subsist, for a while at least, without these rodents. It is not known, however, if they can maintain such a livelihood indefinitely.

K. E. Christiansen informed W. H. Kittams **(unpubl. rept.)** that he saw several ferrets come out of a haystack which was being moved on a ranch in Lyman County in 1964. P. W. Kattenbach, a Washabaugh County rancher, told us he saw a black-footed ferret in an oats strawstack in the late winter and early spring of 1966. He reported that this stack harbored many mice in early winter but that very few remained by late spring. Cahalane (1954-Report No. 29) mentions a nest of four young ferrets in a haystack in Perkins County, and Anthony (1937) states they hunt field mice. William Hespe told us he had a close view of a ferret in a haystack in Haakon County on April 15, 1965. Our investigation the next day failed to reveal any invidence of its continued presence, and Hespe did not see the ferret again. Dono Capp **(pers. com.)** killed a ferret in a haystack in Ziebach County in January 1958, and Russell Allard **(pers. com.)** observed a ferret under a haystack in Washabaugh County in June 1965.

A ferret was caught by a farmer in a rat trap near some farm buildings in Sully County in the summer of 1959 and released (W. H. Kittams **unpubl. rept.**), and a family of ferrets used some deserted sheep sheds as a home (Grinnell 1896). Mrs. John Larsen told us she observed a ferret in some old culverts in a farmyard in Haakon County in April 1965. Nelson (1918) mentions a ferret that stayed for several days under a wooden sidewalk in Hays, Kansas, where it killed rats living there.

On the morning of August 28, 1964, Adrian watched a ferret leave its burrow and chase a thirteen-lined ground squirrel. Two other ferrets emerged from the burrow and joined the chase. The ground squirrel escaped by going down its burrow which was too small for its pursuers to enter. The three ferrets then returned to their burrow. Loras Riggins told us he saw a ferret catch a thirteen-lined ground squirrel in an alfalfa field in Washabaugh County in the summer of 1962. Cahalane (1954-Report No. 16) recorded a ferret seen carrying a thirteen-lined ground squirrel in a prairie dog town, and Roosevelt (1900) mentions they feed on gophers.

Robert Schilder informed us he saw a group of eight black-footed ferrets in a colony of Richardson ground squirrels in Faulk County for a few days in July 1965. H. G. Troester reported to us that he saw a ferret cross a highway in mixed cropland, hayland and pasture near Dawson, N. D. on June 18, 1963. Richardson ground squirrels were present within a mile or so, but prairie dogs are not known to occur nearer than 50 miles west.

Adrian's notes for October 14, 1964, describe an experiment with a desert cottontail. Adrian noticed that a number of prairie dogs were sitting up on their burrow mounds with their attention directed toward a ferret that was looking out of a burrow. After watching the ferret travel from burrow to burrow, Adrian and a companion moved to the last burrow into which the ferret had gone. Adrian's companion thrust a live cottontail with a 10-pound-test fish line attached, down the burrow and held it there for about a minute. When he pulled it out, the rabbit's throat was cut and it showed little sign of life. The ferret stuck its head out of the burrow and peered at the observers for a couple of minutes. Its whiskers were noticeably bloody. The ferret then came out of the burrow and ran into another about 40 yards away. When it went down this burrow, Adrian's companion lowered the rabbit after it again and left it there for about 3 minutes. When he tried to pull the rabbit out, the fish line broke as the ferret apparently held onto the rabbit. By placing his ear at the mouth of the burrow, Adrian could hear the ferret eating the rabbit.

R. W. Gerhardt **(pers. com.)** observed a ferret chase a cottontail down a sheepherder's trail on the afternoon of August 22, 1963, in Carbon County, Wyoming. Roosevelt (1900) lists sage rabbits (probably desert cottontails) and jackrabbits (probably white-tailed jackrabbits) as a source of food, and rabbits and hares are also mentioned by Audubon and Bachman (1851) and by Lantz (1905). Roosevelt (1900) cites an instance of a ferret attacking a fawn pronghorn antelope, but this appears to be an unusual case.

Birds also seem to attract the ferret's attention, perhaps appealing to its curiosity as well as to its predatory nature. On August 23, 1964, Adrian saw a ferret leave its burrow and lie beside the entrance for a minute or so, watching a western meadowlark. It then chased the bird, which flew away. A horned lark landed near the burrow entrance and the ferret chased it. On other occasions a western meadowlark swooped overhead at a ferret, and a killdeer put on a broken-wing act. Both apparently recognized the ferret as an enemy. Baker (1889) states that the ferret makes occasional raids on poultry, and Mrs. Harry Roth told us of a ferret killing chickens in her chicken house near Reliance. The ferret is said to feed on ground roosting birds at night and on burrowing owls in their holes as well as to climb low trees in desert regions to rifle nests or pounce upon roosting birds (Olin 1959). Audubon and Bachman (1851), Roosevelt (1900) and Anthony (1937) also mention birds and their eggs as items in the ferret's diet.

Hollis Young told us he saw a ferret carrying a snake into a prairie dog burrow in Jackson County in May 1965. Small reptiles and snakes are mentioned by Audubon and Bachman (1851) and by Roosevelt (1900) as food items of ferrets.

Ralph Hubbard **(pers. com.)** observed a ferret batting down and eating moths under a street light in Wheatland, Wyoming in 1931 and saw a ferret eating Carolina locusts at Elbert, Colorado, in about 1927. We watched ferrets, particularly young, catch flies in their mouth. This habit has also been reported by George Barnes (**vide** W. E. Garst **pers. com.**).

Although ferrets have been known to live for a time on these other sources of food, they apparently will not do so indefinitely. We spent many hours making biological observations in a variety of habitats other than prairie dog towns. Never once did we see a ferret or its sign even though we were in the known geographic range of the species. We also checked 42 reports by others of ferrets 1 to 5 miles from known prairie dog towns. Although we were satisfied that these people had actually seen a ferret, our observation of the areas and the surrounding vicinity failed to produce a sighting or sign of an animal. From this we conclude that these ferrets were occupying the areas only temporarily. This is further supported by the fact that most of these records occurred in the fall when our studies show ferrets are most apt to be on the move.

A considerable number of people in western South Dakota trap fur-bearing animals, mainly mink. If ferrets were numerous outside of prairie dog towns, presumably some would be caught. Such, however, is not the case.

It should be noted, too, that many of the alternate kinds of food observed to have been consumed by ferrets are not available to them in winter on the northern plains. At that critical period the black-tailed prairie dog remains as the most abundant and readily secured food item.

Enemies. Observations indicate the ferret has several important enemies. One possibly formidable threat, however, was shown to be viewed with seeming indifference. It might be expected that the presence of man would be alarming to this secretive animal. Instead, the authors were amazed at the lack of fear by ferrets, particularly adults, toward humans. In fact, ferrets were quite confiding and curious in their behavior.

When approached closely during the day, ferrets would generally crouch. They would permit a person on foot to come within 40 feet and a person in a car to come even closer before they would retreat down their burrows. Often they would reappear with only their head showing when the observer was 10 or less feet away and would bob up and down in the burrow entrance. At night, ferrets often could be approached to within a few feet. This was particularly true if use was made of a white light which seemed to partially blind the animals. Females while caring for young were less wary than their offspring or ferrets at other times of the year. The only problem in observation was the initial sighting of a ferret. The animals are quite irregular in visits above ground except for the period from first appearance of the young out of their burrow to family dispersal.

When alarmed or disturbed the ferret gives a characteristic chattering or bark and may hiss defiantly. The animal studied by D. R. Progulske (**unpubl. MS.**) was noted by its original captor to have emitted a squealing note when first run down and seized. At times, a ferret may seemingly challenge a human observer but was never seen to actually attack. Dartt (1879), Aldous (1940), Van Riper and Niedrach (1946), W. E. Garst (**pers. com.**) and D. R. Progulske (**unpubl. MS.**), who have studied either wild or captive individuals, have recorded similar findings on the vocalization and temperament of ferrets. On the basis of certain of the published statements of these authors and of Roosevelt (1900) and Seton (1929), some later writers who have never observed a ferret have pictured it as constantly ferocious and irritable. We believe this is an incorrect judgment. Apparently much of the legend on the disposition of the ferret has come from captive individuals which displayed their anger when provoked or from animals in the wild that were harassed or were defending their young. Actually, Dartt's and Aldous's wild-caught specimens readily submitted to handling and became quite tame. However, Aldous's animal later became wilder when given more freedom.

Ferrets do suffer losses from man. Trapping for various purposes accounts for a few accidentally taken animals. Because of the lack of an assured sizeable catch, however, no commercial market has ever been developed for them. In Europe, though, upwards of 100,000 skins of the European ferret were marketed annually as fitch prior to the 1940's (Harding 1943).

Vehicular traffic is responsible for some loss of ferrets each year. Among the 225 reports of ferrets seen dead or alive, 20 are of ferrets almost certainly run over and killed by motor vehicles on roads. Undoubtedly, many more ferrets have been killed in this manner, and the deaths have been unreported.

Man when he shoots prairie dogs is also a threat to the black-footed ferret. Prairie dog shooting is a popular sport in many places. Some hunters pride themselves on their ability to hit a prairie dog at 200 yards. At such a distance, regardless of the hunter's visual acuity, a ferret peering out of a burrow would be difficult to identify. Some hunters report having killed a ferret because the animal "looked different" and they wanted a closer inspection. Many ferret shootings probably have not been reported because a deliberate killing is a violation of South

Dakota law. Even if the shooting had been accidental, the injured or dead ferret would often disappear down the burrow, leaving no sign of its presence. Lantz (1905) points out that many sport hunters in Kansas persistently killed ferrets whenever they saw one.

Man's greatest threat to the ferret, however, is an indirect one resulting from his destruction of prairie dogs on which ferrets depend for food and shelter. This may have started with reduction by commercial hunters of the bison herds, which through their grazing and trampling activities provided conditions favorable to prairie dogs. However, introduction of domestic livestock probably has compensated at least in part for this influence. More recently man has poisoned prairie dogs or has destroyed their habitat by tillage and other land-use practices.

Prairie dog poisoning has been accomplished with a variety of chemicals but the most effective are strychnine and 1080. They are applied to oats or other grains and distributed at the rate of about 0.04 ounce of actual strychnine (U. S. Dept. Int. 1956) and 0.01 ounce of actual 1080 (C. E. Faulkner **pers. com.**) per acre. The minimum lethal oral dose of 1080 to domestic European fitch ferrets (Marshall 1963) is 1 mg/kg. The level that kills all black-tailed prairie dogs is less than 0.9 mg/kg (Ward and Spencer 1947). We found no data on the toxicity of strychnine to prairie dogs and ferrets. However, lethal oral doses for dogs and cats vary from 0.3 to 1.2 mg/kg, and median lethal oral doses for white rats vary from 5 to 16.2 mg/kg (Spector 1956). Hillman (1968) showed that domestic fitch ferrets died following several feedings on the viscera of prairie dogs killed by eating 1080-poisoned oats. Prairie dogs ordinarily would acquire more than a lethal dose in their feeding on poisoned oats. Hence, a ferret might be poisoned by eating less than all of the parts of a prairie dog containing the poison.

Another probable enemy of the ferret is the badger. On the night of July 9, 1965, a badger entered a part of a prairie dog town where young ferrets were outside their burrow. The mother ferret made a barking sound closely resembling that of a prairie dog. This attracted the badger's attention as it dug into the burrow where the young ferrets had retreated. The badger turned to chase the mother ferret, which disappeared down a burrow located 120 feet from the burrow of the young. The badger then began to dig into the burrow down which the adult ferret had fled. Adrian approached to within a few inches of the badger and took photographs, after which it left the town. It is not known if this burrow had another opening that the ferret could have used as an emergency exit. W. E. Garst (**pers. com.**) recorded an instance in which a badger plugged the entrance of a burrow in which a ferret was heard. The next day the burrow had been dug open from the inside.

The domestic dog definitely seems to be an enemy of the ferret. Three reports of ferrets having been caught and killed by dogs were received from widely scattered localities during an 8-month period: an adult female killed by a dog in Haakon County on September 29, 1965; an adult male killed by dogs in Todd County on March 7 or 8, 1966; and a ferret killed by a dog near a prairie dog town in Jones County in May 1966.

The coyote is also a probable enemy of the ferret. Remains of ferrets were found in 3 of 8,339 coyotes taken with food in their stomachs in western states (Sperry 1941). Some of these coyotes were taken in areas where ferrets were not known to occur. Coyotes commonly hunt prairie dog towns and thus would be apt to encounter ferrets at times.

Two young ferrets were killed by a domestic cat (Cahalane 1954, Report No. 22). Bobcats were noted on prairie dog towns on four different occasions during this study.

Attempted predation by a great horned owl was described in the section on "Senses." In addition, Dale Richardson told us he saw a ferret that was being chased by an owl, run in front of his automobile in Jones County at approximately 3 a.m. on May 16, 1967.

Ralph Hubbard (**pers. com.**) found the dried and badly mutilated remains of a ferret in a golden eagle's nest in the fall of 1912 near Harlowton, Montana. Eagles had used the nest in the spring.

Other potential avian predators of the ferret include the snowy owl and various hawks. On November 11, 1964, at 11:30 a.m., Adrian noted that a ferret which had emerged from a burrow suddenly stopped. At that time a rough-legged hawk lit in the prairie dog town. The prairie dogs began barking an alarm, and the ferret went down a burrow. A ferret sunning itself with its eyes closed would appear to be in danger of predation by raptors. However, this incident indicates that ferrets probably rely on their hearing and the reaction of prairie dogs to warn them of avian hunters.

Prairie rattlesnakes and bull snakes may prey on ferrets at times, but no incidents have been reported.

The young and the adult ferrets in the "south" town in Mellette County seemed to be bothered by external parasites and frequently scratched themselves. Flies, ticks and prairie dog fleas were normally abundant in and around prairie dog burrows used by ferrets. Four ticks on the neck of an adult ferret are shown in Figure

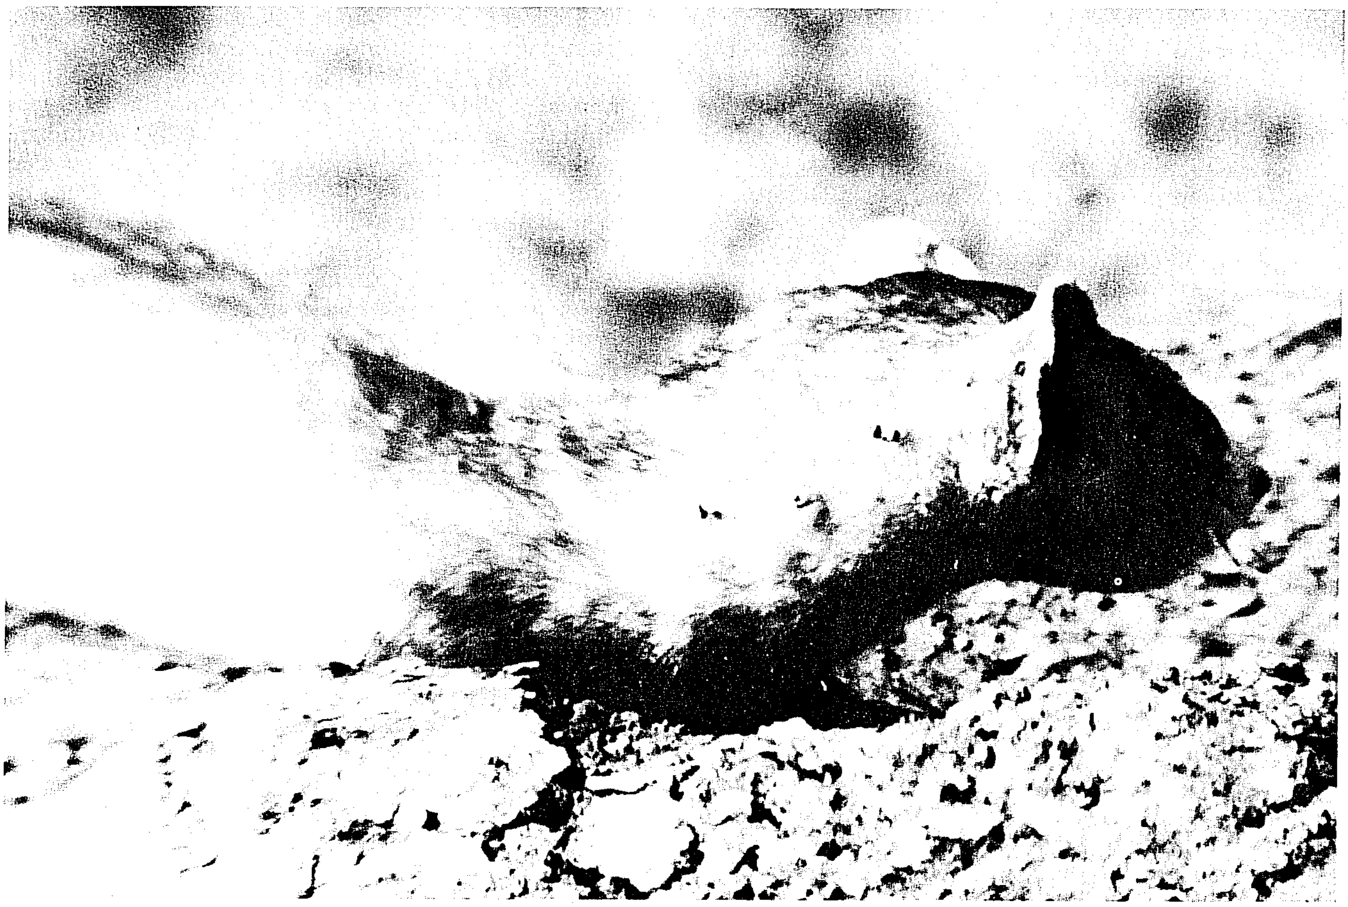

Figure 30. Ticks on neck of adult female black-footed ferret. Mellette County, South Dakota, July 29, 1966. (Henderson)

30. Boddicker (1968) identified the prairie dog flea, a tick **(Ixodes kingi)** and a nematode **(Molineus mustelae)** from three ferrets but found no parasites from four specimens. He also recovered two species of non-parasitic mites. Emerson (1964) lists the louse **(Neotrichodectes minutus)** as a parasite of the ferret.

Little is known about the diseases of black-footed ferrets. The ferret studied by D. R. Progulske **(unpubl. MS.)** was captured in August 1961 as a young animal and held at a mink ranch and later in an outdoor pen containing 12-15 inches of soil and a den box. It died of pneumonia on February 2, 1964. Gorham et al. (1965) describe the diseases and parasites of mink, and Harding (1943) some of those of the domestic European fitch ferret. The longest recorded life span of a black-footed ferret is 5 years for a captive individual (Mann 1930).

LOCATING FERRETS

Solicitation of ferret reports is one of the most efficient means of obtaining potential information on the species within a given area. This may be accomplished by the use of pictures sent to residents in possible ferret areas and published in newspapers and state conservation magazines. For best results it should be accompanied by a brief explanation of the objectives of the survey and of the animal's habits. The color postcards used in this investigation were very effective in prompting the submission of reports.

Since prairie dog towns are the usual residence of the black-footed ferret, the use of a light plane flying at an altitude of 300 to 500 feet is helpful in locating active towns and plotting them on a map. This search may be conducted at any time of the year. However, prairie dog towns are most readily located in the early spring because they "green up" earlier than the surrounding grassland.

Winter is one of the best times for observing signs of ferret activity in prairie dog towns since ferret tracks and digging are most evident in fresh snow. Furthermore, prairie dogs are less active in the winter and not as apt to erase signs of ferret digging. However, snowfalls occur irregularly in western South Dakota. Furthermore, winds easily blow the open prairie land clear of snow or pack the snow so that tracks are not easily visible. Because of its maneuverability a helicopter is probably the most expedient means of surveying a large number of prairie dog towns. However, the operating costs of such equipment are normally high. Therefore, an airplane equipped with skis might be substituted. By flying at elevations of 100 to 200 feet over possible ferret sites, the investigator might easily spot ferret tracks and trenches in fresh snow. Upon sighting possible ferret sign the observer might safely land an airplane in the super-cub class near almost any prairie dog town in South Dakota for a closer inspection from the ground.

In conducting ground surveys of towns during daylight hours the following procedures have been most successful. Approaching to within 100 yards of the area, the investigator should inspect the town through a spotting scope, preferably 15x, or binoculars. It is especially important to note the activity of prairie dogs if any are out. If a ferret is looking out of a burrow or has recently descended a burrow, prairie dogs will not graze peacefully in their normal fashion. Instead, they will usually sit up erectly at their burrow entrance looking in the ferret's direction. They become especially excited and move toward the ferret if it is active above ground. If the ferret goes down a burrow, they will attempt to cover it. It is best to make these initial surveys from a vehicle. Prairie dogs are less wary of the investigator under this condition than if he is on foot.

If observation of prairie dog behavior for 30 minutes yields no indication of a ferret the investigator might profitably proceed as follows: move to the edge of the town and inspect again for 15 to 20 minutes; then, walk or drive around and through the town, looking for ferrets and their sign. The observer should stop occasionally to inspect the area through binoculars. During this survey he may estimate the size of the town.

If this ground search is being conducted in winter, one should look for ferret tracks in the snow or for signs of the playful behavior previously described (snowslides and tunnels, in particular). Burrow openings should be scanned for signs of recent ferret diggings and trench formations. Although ferret scats are rarely found, this sign should not be forgotten.

In addition to signs of digging and trenching, an investigator in summer should note if the town has many freshly covered burrow entrances. Prarie dogs, while usually less active during the winter, will spend many daylight hours at other times of the year plugging burrows in areas where ferrets have been active. During the late spring and early summer the investigator should also notice if the prairie dog population includes as many young prairie dogs as would be expected in a ferret-free prairie dog town. It has been observed that prairie dogs residing in a part of a town occupied by ferrets are more nervous and apt to descend their burrows more readily than those in ferret-free towns. However, this is also true of prairie dogs that have been shot at by hunters.

Nighttime surveys should also be made since the ferret is primarily nocturnal. Mother and young are seen above ground most nights from early July to early September. The principal hours of activity are from the period after twilight to midnight and from 4 a.m. to an hour or so after sunrise (Hillman 1968). A spotlight equipped with a 100-watt aircraft landing bulb is useful in night surveillance. It is best to shine the light back and forth over the same area. A ferret sometimes turns its head away from the light and may not be otherwise discernible except at close distances. The reflection of an artificial white light from a ferret's eyes is brilliant to moderate green and may be detected at distances up to 200 yards. The reflection from a white-tailed jackrabbit or cottontail is amber while that from a badger is light green.

A ferret is usually disturbed by a bright white light. A red filter placed over the light after a ferret is located reduces this annoyance. Also, positioning one's self downwind from the area of observation ensures more normal ferret behavior. Use of an Army infrared snooperscope is not satisfactory for observing ferrets at night. Improved infrared detectors now developed by the Army probably would be more satisfactory. However, this equipment has not been released for civilian use.

Sometimes it is possible to call a ferret out of a burrow by imitating the distress call of a rabbit or prairie dog or the note the mother uses for the young to follow her. This is especially useful if a ferret is known or suspected to be in a particular burrow.

In our opinion, unless ferrets are actually seen, there is no way to be certain that a ferret is living in a prairie dog town at a particular time. Finding any sign characteristic of ferrets should encourage the investigator, but he should keep in mind the similarity of mink sign. The following additional information which can be gathered from nearby residents may also prove helpful in determining the status of ferrets in a prairie dog town: (1) how long has the town been at its present location, (2) is it increasing or decreasing in size, (3) do people shoot at the prairie dogs often, (4) has any poisoning of prairie dogs been attempted, and (5) has anyone seen a ferret or its sign in the town? If the investigator finds sign or if other evidence indicates that further surveillance is warranted, we suggest that the investigator watch and search the town up to 5 consecutive days and nights from 3 hours before dusk until 3 hours after dawn. A two-man team permits observers to alternate.

Towns uninhabited by prairie dogs probably will not yield a ferret. However, they sometimes may be profitably investigated for remaining indications of former ferret presence.

DISCUSSION AND CONCLUSIONS

Black-footed ferrets reportedly have been rare since the species was discovered. This has been due in part to their predominantly subterranean and nocturnal habits accompanied by a lack of concerted effort to find animals and an inability to recognize ferret sign. Surprisingly, however, we uncovered considerably more South Dakota records made during the period preceding the initiation of this study than were generally known to exist. As a result of our investigations, an increased knowledge of ferret habits and sign was obtained. This coupled with greater publicity given to ferret reporting, particularly among ranchers, resulted in many new valid records, in the 4 years from 1964-1968. Obviously ferrets are not as rare in South Dakota as was formerly thought. However, all indications are that they never have been a common species.

Some ferrets persist for a time in situations, such as haystacks, in which prairie dogs are absent. There is no evidence, however, that ferret occupancy separate from prairie dog areas in South Dakota is either extensive or increasing. Whether disappearance of ferrets from such areas is the result of an uncertain food supply, lack of ready-made burrows, or innate behavior patterns is unknown.

Based on present animal control attitudes and philosophies the outlook for the prairie dog on private land is not bright. Some private landowners tolerate small numbers of prairie dogs, and a few commercial establishments feature prairie dog towns as tourist attractions. However, many landowners desire eradication of the prairie dog and either do it themselves or ask for government assistance. In addition, pressures exist for governmental control of prairie dogs on many Indian reservations and on certain public lands.

Before man undertakes any large-scale intensive program for control of any organism, he should know the impact of that program on other organisms. If dangers exist, adequate steps should be taken to keep them at a tolerable level. Removal of any native species might have far-reaching effects on the other members of the ecological community since each is related to the rest. We still have much to learn about the prairie dog and its relationship to the rest of the prairie community. We know even less about the black-footed ferret. However, all information available to us indicates a close association of the two species in South Dakota and perhaps even a necessary dependency of the ferret upon the prairie dog if the ferret is to exist in any numbers. Therefore, we conclude that a program for preservation of ferrets becomes, as well, a program for retention of adequate numbers of prairie dogs.

In order to preserve the ferret, we recommend the following over-all program:

1. Continue and intensify studies into the status, life history and ecological relationships of ferrets, prairie dogs, and other ferret prey. This should include development of methods to live-trap and mark ferrets and investigations of marked ferrets to learn their movements and longevity.
2. Continue efforts to develop better methods for determining the presence of ferrets.
3. Urge increased reporting by the public of live and dead ferrets and of ferret sign. Reports should be sent to the South Dakota Department of Game, Fish and Parks at Pierre 57501 or to the Bureau of Sport Fisheries and Wildlife, Ferret Biologist, 919 Main, Rapid City, South Dakota 57702, or given to employees of the Department or Bureau.
4. Promote greater public awareness of the dependency of ferrets upon prairie dogs.
5. Determine the direct and indirect effect of prairie dog control on ferrets.
6. Develop materials for prairie dog and other animal control that will not poison ferrets.
7. Explore all feasible means of retaining adequate numbers of prairie dogs and ferrets on both public and private lands.
8. Experiment with transplanting and releasing ferrets into areas where prairie dogs are protected.
9. Test methods for maintaining ferrets in areas not occupied by prairie dogs.
10. Employ a state wildlife biologist to study non-game animals, including ferrets.

The black-footed ferret is protected in South Dakota. No one except authorized personnel may hunt, take, trap or kill a ferret, and then only under severe restrictions. In regard to prairie dogs, no control may be undertaken on national wildlife refuges of the U. S. Bureau of Sport Fisheries and Wildlife without permission of the Regional Director of that region. Further policy issued June 22, 1965, states that U. S. Department of the Interior personnel may not undertake prairie dog control until surveys are conducted and the areas are certified to be free of ferrets. The U. S. Department of Agriculture and the Defense Department are also cooperating by generally requiring pre-control surveys on lands under their jurisdiction.

The present method of pre-treatment survey is by vehicle or on foot. Our studies have shown that the occurrence of ferrets or their sign varies considerably. Even the most qualified observer cannot make a survey of a prairie dog town in a limited time and always say with full assurance that ferrets are not present. We watched two different towns for a 5-day period and saw ferrets on several nights. However, these ferrets left no visible sign during this time. To be sure that a ferret does not occupy a prairie dog town, we believe a survey crew should plan on spending up to 5 consecutive days and nights observing the town.

Necessary control rather than eradication of prairie dogs is the current objective of the Bureau of Sport Fisheries and Wildlife. Also, under a new experimental policy announced April 27, 1967, the Bureau will not attempt to achieve complete prairie dog control by follow-up poisoning if the first treatment achieves approximately 90 per cent control.

We have found that landowners who wish to control prairie dogs in towns on their property that are harboring one or more ferrets are sometimes satisfied to forego poisoning when it is explained to them that ferrets eat prairie dogs and are able to stabilize or reduce prairie dog populations.

If land where prairie dog control is desired is leased from a government agency for grazing, it may be possible to lower the cost of the lease to a level commensurate with the current value of the land for cattle. This would tend to reduce the pressure for increased prairie dog control on land that is overevaluated.

In key private areas another approach might be to lease the rights from the landowner not to poison the town. This would be similar to governmental programs of leasing the rights not to drain, fill or burn wetlands. At present, governmental agencies do not have funds set up specifically for a lease program of non-poisoning. However, such an approach is possible under the federal Rare and Endangered Species Program. In addition, some private conservation organizations might have limited funds that could be used to lease non-poisoning rights in important areas.

If prairie dog poisoning is undertaken, treating only the perimeters of towns to prevent their further increase in size is preferable to complete poisoning.

Accurate information on the home range of ferrets still does not exist. However, we believe restricting placement of poison for control of prairie dogs and other animals within a 5-mile radius of any known ferret location should give adequate protection to ferrets.

More study is needed of the secondary effects of present prairie dog poisoning programs on ferrets. In addition, increased steps should be taken to develop materials that do not jeopardize non-target species. In this regard the report of the Secretary of the Interior's Advisory Board on Wildlife Management (Leopold 1964) recommended that legal means be explored to ban the distribution and use of 1080 as a poison for field rodents and that such control be conducted with other chemicals which are not readily transmitted to scavenging animals.[1]

One way of providing prairie dog towns for ferrets is on governmental parks and refuges. In South Dakota some of these areas are Custer State Park, Badlands National Monument, Wind Cave National Park, Lacreek National Wildlife Refuge, several National Grasslands and National Forests administered by the U. S. Forest Service, lands under the trusteeship of the Bureau of Indian Affairs, and lands administered by the Bureau of Land Management. An attempt should be made at an early date to inventory and estimate the numbers of ferrets and prairie dogs now present on these areas. If ferrets are found near these lands, the possibility of public acquisition should be ascertained. At times some governmental lands are determined to be in excess to the public need. It is recommended that they not be transferred to private interests if they have ferrets or conditions suitable for the establishment of prairie dog towns in which ferrets could reside.

No ferrets are now known to exist in Custer State Park, Badlands National Monument or Wind Cave National Park. Since these areas have protected prairie dog towns, it is recommended that they be stocked with ferrets at some future time if surplus animals can be found in other areas. Such animals should be marked to provide information on their movement and longevity.

The Bureau of Sport Fisheries and Wildlife under the Rare and Endangered Species Program has a biologist who, since February 1966, has been assigned full time to studies on ferret. These include investigations of status and movements of ferrets, improved survey methods, and determination of effects of prairie dog control programs on ferrets. However, more effort is needed. In addition the state of South Dakota has increasing interest in pest animal control. For these reasons the employment of a state biologist to work on ferrets and other non-game species is recommended to develop pest control programs.

For over a century the black-footed ferret has remained shrouded in mystery. As a result of this study we have gained new insight into the habits of this animal and its relationship to various facets of its environment including the prairie dog control program. Although additional knowledge is needed on some points, we presently possess much of the basic information necessary to manage this species for the future. The moral responsibility of all men to see that the black-footed ferret is allowed to remain a part of our original prairie heritage is now at hand.

---

1. The Bureau of Sport Fisheries and Wildlife no longer uses 1080 for prairie dog control.

Ferret Specimens and Sightings In South Dakota From 1889 To 1967

1889

1. 1889 — skin seen, animal not common — Pine Ridge Agency, Shannon County. Reported by A. B. Baker. Bureau of Sport Fisheries and Wildlife records.

1894

2. 1894 — reported to be plentiful — Sand Ridge, north of Cheyenne River, between its mouth and the fork, Dewey and Ziebach Counties. Recorded by Vernon Bailey. Bureau of Sport Fisheries and Wildlife records.

1903

3. 1903 or 1904 — one — Gillette Canyon, Custer County. Observed in prairie dog town by James P. Campbell. Recorded by Merritt Cary. Bureau of Sport Fisheries and Wildlife records.

1904

4. 1904 — one — Indian Draw near Sheep Mountain, Pennington County. Observed by Abraham Jefferson. Recorded by Merritt Cary. Bureau of Sport Fisheries and Wildlife records.

1905

5. About 1905 — two — Okobojo, Sully County. Pair came in and cleaned out prairie dog town. Reported by J. W. Glessner. Recorded by Merritt Cary. Bureau of Sport Fisheries and Wildlife records.
6. Spring — four — Bailey (S 26, T 109 N, R 70 W), Hand County. Trapped by G. F. Moon. Pair sold alive and two mounted (Moon 1905 and Anon. 1906).
7. Winter — 1905-1906 — one — southern Bennett County just across state line from Merriman, Nebraska. Killed and mounted by L. Sessions. Bureau of Sport Fisheries and Wildlife records.

1907

8. About 1907 — more than one — Rosebud Indian Reservation; Mellette, Todd and Tripp Counties (Reagen 1908).

1908

9. 1908 — unspecified number — Okobojo Creek, Sully County. Ferrets destroyed prairie dogs in immense town. Reported by S. W. Glenn. Bureau of Sport Fisheries and Wildlife records.

1913

10. January 10 — one — Box Elder, Pennington County. Collector unknown. Specimen J 23 mounted, W. H. Over Dakota Museum, University of S. D. Recorded by Byron E. Harrell.

1915

11. August 22 — male — labelled Pine Ridge (Indian) Reservation, White River, Mellette County. Collected by R. A. Ward. Specimen 209150, U. S. National Museum. Recorded by Paul F. Springer.
12. October — one — Badlands, Pine Ridge Indian Reservation, northern Shannon County. Observed by H. H. Sheldon. Bureau of Sport Fisheries and Wildlife records.

1920

13. October 4 — male — Interior, Jackson County. Trapped in prairie dog town by Bud Dalrymple. Bureau of Sport Fisheries and Wildlife records.

1921

14. February 11 — male — along Cheyenne River near Scenic, Pennington County. Trapped in prairie dog town by Bud Dalrymple. Bureau of Sport Fisheries and Wildlife records.

1922

15. Spring — one — Wind Cave National Park, Custer County. Observed in prairie dog town by Troy C. Beach. (Hot Springs (S. D.) Times Herald; April 21, 1922.)

1923

16. 1923 — one — along Eagle Nest Creek, Washabaugh County. Trapped in prairie dog town by Vetal Romero. Recorded by F. Robert Henderson.
17. September 16 — one (sex not stated) — Pine Ridge, Shannon County. Collected by D. P. Stearns. Specimen 243799, U. S. National Museum. Recorded by Paul F. Springer.
18. November 1— male — Govert, (S15, T15N, R8E), Harding County — collected by Louis Knowles. Specimen 243990, U. S. National Museum. Recorded by Paul F. Springer.

1925

19. Before November 5 — female — Pine Ridge, Shannon County. Specimen 241014, U. S. National Museum. Recorded by Paul F. Springer.
20. December 24 — male — T 2 S, R 12 E, Pennington County. Trapped by Mr. Rockwell. Submitted by Ray E. Lemley. Specimen 70590, American Museum of Natural History. Recorded by Richard G. Van Gelder.

1927

21. September 5 — female — 18 miles southeast of Rapid City, Pennington County. Collected in prairie dog town along Spring Creek by Henry Behrens, Sr. Specimen mounted, Augustana College, Sioux Falls. Recorded by Paul F. Springer.
22. Winter — one — near Conata, Pennington County. Collected in prairie dog town by Thad Bennett. Specimen J155, Zoology Department, University of S. D. Recorded by Byron E. Harrell.

1930's

23. 1930's — several — northeast of Lantry along Moreau River, Dewey County. Observed in prairie dog town by Wesley E. Ernst. Recorded by Fred Priewert.
24. 1930's — one — 17 miles northeast of White River, Mellette County. Observed in prairie dog town by Albert Jans. Recorded by Paul F. Springer and Conrad Hillman.

1931

25. Spring — several — Crow Creek Indian Reservation, probably Buffalo County. Observed by Tom J. Turner.
26. December 31 — male — near Hermosa, Custer County. Trapped in prairie dog town by Fred M. Dille. Specimen ZM 4451, University of Nebraska Museum. Recorded by Paul F. Springer.

1937

27. 1937 — one — T 4 N, R 15 E, Pennington County. Observed in prairie dog town by Evan McDonald. Recorded by F. Robert Henderson.

1940

28. Fall — one — T 16 N, R 15 E, Perkins County. Found dead on road in prairie dog town by Earl Engelbretson. Recorded by Paul F. Springer.

1946

29. 1946 or 1947 — male — T 19 N, R 23 E, Corson County. Trapped by John Steel. Recorded by Paul F. Springer.
30. November — male — Lyman County. Collected in prairie dog town by Adrian Lester. Specimen 33434, State University of Iowa. Recorded by Walter C. Thietje.

1947

31. About July 15 — one — T 2 S, R 22 E, Jackson County. Ferret picked up a shot prairie dog and took it down a burrow. Observed by A. Orville Sandall.

1948

32. Spring — one — near Chamberlain, Brule County. Recorded by James T. McBroom. (Cahalane 1954, Report No. 30).

1949

33. About 1949 — one — near Mud Butte, Meade County. Observed by Clarence Allen. Recorded by Douglas R. West.

1950

34. Summer — six — north of Parmelee, Rosebud Indian Reservation, Todd and Mellette Counties. Observed in prairie dog towns by Walter J. Stammerjohn. Recorded by Harold H. Haecker. (Cahalane 1954, Report No. 23).
35. Summer — one — on Baxter Berry ranch between Norris and Belvidere, Mellette County. Observed in prairie dog town by Ralph Block.
36. Summer — one — fork of White River, northeast of Blackpipe Day School, Mellette County. Observed in prairie dog town by Ralph Block.
37. October — two — 12 miles south of Isabel, Dewey County. Observed in prairie dog town by Ralph Block; one male shot. Specimen 285877, U. S. National Museum. Recorded by Paul F. Springer. (Cahalane 1954, Report No. 25 corrected).

1951

38. 1951 or 1952 — one — T 114 N, R 79 W, Sully County. Observed along creek by E. R. Lamster.
39. 1951 or 1952 — one — Wessington Springs, Jerauld County. Trapped by unknown person. Reported by Robert N. Randall. Recorded by John L. Sypulski. (Cahalane 1954, Report No. 32).
40. Summer — at least two — north of Rosebud Indian Agency, Mellette County. Observed in prairie dog town by Harvey Gibson. Recorded by Harold H. Haecker. (Cahalane 1954, Report No. 26).
41. Summer — one — northwest of Oglala, Pine Ridge Indian Reservation, Shannon County. Observed in prairie dog town by Ralph Block. (Cahalane 1954, Report No. 24 corrected).
42. Summer — one — near Kyle, Pine Ridge Indian Reservation, Shannon County. Observed in prairie dog town by Ralph Block. (Cahalane 1954, Report No. 24 corrected).
43. Fall — one — near Mobridge, Walworth County. Trapped by unknown person. Recorded by James T. McBroom. (Cahalane 1954, Report No. 31).
44. November — one — Okobojo Creek, Sully County. Shot by unknown person. Reported by John W. Leete. Recorded by John L. Sypulski. (Cahalane 1954. Report No. 33).

1952

45. Summer — two — north of Cheyenne River, Meade County. Trapped in prairie dog town by unknown person. Reported by Roy L. Clennon. Recorded by Oren Bates. (Cahalane 1954, Report No. 34).
46. Summer — four young — south of Lemmon, Perkins County. Observed in nest in haystack by unknown person. Reported by W. L. Johns. Recorded by Harold H. Haecker. (Cahalane 1954, Report No. 29).
47. Summer — six — eastern Pennington County including two in Conata Basin, T 3 S, R 16 E. Observed in prairie dog town by George Barnes. Recorded by Harold H. Haecker. (Cahalane 1954, Report No. 28). Female specimen 287321, U. S. National Museum, from Conata Basin is probably one of these animals.
48. Summer — six — on Pine Ridge and Rosebud Indian Reservations, Shannon, Washabaugh, Todd and Mellette Counties. Observed by Harvey Gibson. Recorded by Harold H. Haecker. (Cahalane 1954, Report No. 27).
49. Summer — one — 5 miles northeast of Philip, Haakon County. Observed in prairie dog town by unknown person. Reported by W. H. Zimmerman. Recorded by M. S. McMurtrey. (Cahalane 1954, Report No. 37).
50. October 23 — female — 4 miles north of North Fork of Moreau River near Zeona, Perkins County. Run over on road by brother of Alfred Hinds. (Young 1954). Specimen 3667 mounted, J. F. Bell Museum of Natural History, Mpls. Recorded by Paul F. Springer.

1953

51. Early July — two adults — 11 miles east of Howes, Ziebach County. Observed in prairie dog town by Ralph Block. One young sighted with adults in same place 2 weeks later. (Cahalane 1954, Report No. 35).
52. July — one — along Bull Creek, 2 miles northeast of Howes, Meade County. Observed in prairie dog town by Ralph Block. (Cahalane 1954, Report No. 36).
53. July 30-August 11 — six — T 1 N, R 24 E, Haakon County. Five trapped in prairie dog town by George Barnes; believed to be adult and four young. Two died in captivity but two males and a female were released in Wind Cave National Park, Custer County. One animal shown in film "Vanishing Prairie." (Garst 1954; Cahalane 1954, Report No. 38).
54. September — one — U. S. Highway 14, 1 mile west of Midland, Haakon County. Found dead on road by Ben Buell. Recorded by George Barnes.

1954

55. About 1954 — one — T 10 N, R 15 E, Meade County. Run over and stunned by William Jordan. Put in barn but escaped. Recorded by Douglas R. West.
56. March 24 — male — U. S. Highway 14, 15 miles north of Midland, Stanley County. Found dead on road by Bernard A. Nelson.
57. August — one — 7 miles northeast of Kadoka, Jackson County. Observed in prairie dog town by James Judge. Recorded by Harold H. Haecker.
58. November — male — near Moreau River, 14 miles northwest of Dupree, Ziebach County. Trapped by Robert Burgee.
59. November — male — near Red Elm, Ziebach County. Killed on trail by Robert Burgee.
60. Late fall — female — T 17 N, R 23 E, Dewey County. Shot ½ mile from prairie dog town by Ed Bickel.

1955

61. About 1955 — one — 15 miles south of Kennebec, Lyman County. Found dead on road by Kenneth E. Christensen. Recorded by Walter H. Kittams.
62. About 1955 — one — T 8 N, R 16 E, Meade County. Run over on road by Henry McKay. Recorded by Paul F. Springer.
63. About 1955-1958 — two — 7 miles north of White River, Mellette County. Animals caught in prairie dog town by Charles Larson but escaped. Recorded by William Pullins and Walter H. Kittams.
64. April 13 — one — 16 miles northwest of Jordan Junction, Tripp County. Observed in prairie dog town by John L. Seubert.
65. September — one — T 14 N, R 25 E, Dewey County. Observed in den along Goose Creek by Harold H. Haecker.

1956

66. About 1956 or 1957 — two — 17 miles north of Camp Crook, Harding County. Observed in prairie dog town by Einer Juntti. Recorded by Robert Murphy and Walter H. Kittams.
67. Summer — one — T 22 N, R 29 E, Corson County. Observed in prairie dog town by Ralph Block.
68. Mid summer — one — west edge of Madison, Lake County. Sick ferret found in granary by farmer; died the next day. Skin in Wilbur C. Foss Collection.
69. August 1 — one large and two small ferrets together plus another small ferret nearby — T 20 N, R 28 E, Corson County. Observed in prairie dog town by Walter J. Stammerjohn.
70. Fall — one — Cedar Pass, Badlands National Monument, Jackson County. Observed killing cottontail rabbit near prairie dog town by Tom Boothroyd. Recorded by Walter H. Kittams.
71. Fall 1956 or 1957 — one — about 7 miles west of Gettysburg, Potter County. Reported in prairie dog town by Walter Larsen. Recorded by Walter H. Kittams.

1957

72. About 1957 — one — 7 miles south of White River, Mellette County. Trapped in prairie dog town by Rollie Johnson. Recorded by William Pullins and Walter H. Kittams.
73. About 1957 — one — near Presho, Lyman County. Observed crossing road in evening by Robert Zimbelman. Recorded by Walter H. Kittams.
74. July — one — T 17 N, R 21 E, Ziebach County. Observed by Ed Bickel. Recorded by Paul F. Springer.
75. About August 28 — four (believed to be two adults and two young) — T 41 N, R 33 W, Washabaugh County. Observed in prairie dog town by William Pullins.
76. September — six — about 22 miles west of Onida, Sully County. One shot by landowner in 80-acre prairie dog town. Reported to Ernest Giese.
77. September — one — 8 miles southwest of Agar, Sully County. Observed in a 5-acre prairie dog town by Ernest Giese and Charles Cadieux.

78. September — three — about 18 miles southwest of Onida, Sully County. Observed in 100-acre prairie dog town by unknown person. Recorded by Ernest Giese.

1958

79. About 1958 — one — 12 miles northwest of Highmore, Hyde County. Observed fighting with prairie dog by Joe Stranski. Recorded by Paul F. Springer.
80. About 1958 — one — near Seven Mile Corner, Jackson County. Found dead on road by Jack Hansen. Recorded by F. Robert Henderson.
81. About 1958 or 1959 — one — 27 miles west of Onida, Sully County. Observed in prairie dog town by R. M. Hinsey. Recorded by John Hunter and Walter H. Kittams.
82. January — male — 5 miles southeast of Faith, Ziebach County. Observed in haystack by Dono Capp. Recorded by Douglas R. West. Skin in Douglas R. West Collection.
83. Summer — adult male — U. S. Highway 16, 2 miles west of Reliance, Lyman County. Found dead on road by Robert F. Wahlin.
84. Summer — one — 2 miles east of Sitting Bull Monument, Walworth County. Observed in prairie dog town by Ralph Block. Recorded by Walter H. Kittams.
85. Summer — one — near Midland, Haakon County. Found dead on road by Jack Huston. Recorded by John Hunter and Walter H. Kittams.
86. Fall — one — on Pat Parkening ranch, northwest of Reliance, Lyman County. Observed in prairie dog town by Robert F. Wahlin.
87. Fall — male and female — 20 miles southeast of Faith, Ziebach County. Caught in prairie dog town by Don Thompson. Female released after killing male. Two others caught next spring. Recorded by Walter H. Kittams.
88. September — one — White River, Mellette County. Killed by domestic dog in prairie dog town at edge of city. Observed by Alfred Bartlett. Recorded by William Pullins and Walter H. Kittams.
89. Winter 1958-1959 — one — 15 miles south of Kennebec, Lyman County. Found dead in mink trap by Kenneth E. Christensen. Recorded by Walter H. Kittams.

1959

90. About 1959 — male — 10 miles south of White River, Mellette County. Shot in prairie dog town by Ted Johnson. One of the lower canine teeth had grown out forward from the mouth, but ferret was in good condition. Recorded by F. Robert Henderson and Richard Adrian.
91. Spring — one — near Ideal, Tripp County. Observed in 30-acre prairie dog town by Harold Davis and Lloyd Oldenburg. Recorded by Walter H. Kittams.
92. Summer — one — near Agar, Sully County. Caught in and released from rat trap on turkey farm. Recorded by Walter H. Kittams.
93. Summer — one — T 41 N, R 34 W, Washabaugh County. Observed near prairie dog town by Paul Brunch's son. Recorded by Walter H. Kittams.
94. Summer 1959 or 1960 — four — near Midland, Haakon County. Observed on road at night by Jack Huston. Recorded by John Hunter and Walter H. Kittams.
95. Fall — one — between Longvalley and Norris, Washabaugh County. Observed along road by Paul Brunch. Recorded by Walter H. Kittams.
96. Fall — adult male — 12 miles west of Agar, Sully County. Found dead on road, ¾ mile from 80-acre prairie dog town by Orville VonWald. Recorded by Tal Lockwood. Specimen mounted, S. D. Department of Game, Fish and Parks.
97. Fall 1959 or 1960 — one — near Midland, Haakon County. Observed standing along side of road by Jack Huston. Recorded by John Hunter and Walter H. Kittams.
98. September — one — 2 miles north of Maurine, Perkins County. Found dead on road in prairie dog town by Dale Haines. Recorded by William Pullins and Walter H. Kittams.
99. September 24 — three — along Okobojo Creek about 25 miles southwest of Onida, Hughes County. Observed in 30-acre prairie dog town by Floyd brothers. Recorded by Dean Badger and Walter H. Kittams.

1960

100. About 1960 — one — northeast of Gregory, Gregory County. Killed by domestic dog. Observed by Lloyd Gilbert. Recorded by Richard Adrian.
101. 1960 or 1961 — one — 10 miles south of Highmore, Hyde County. Observed in prairie dog town by Mrs. Joe Stranski. Recorded by Paul F. Springer.
102. Summer — one — on Albert Larson ranch southeast of Reliance, Lyman County. Observed in prairie dog town by Robert F. Wahlin.
103. Summer — one — T 41 N, R 35 W, Washabaugh County. Found dead on road by Wayne Allen. Recorded by Richard Adrian.
104. Late summer — one — 5 miles north of Red Elm, Ziebach County. Observed in 60-acre prairie dog town by Robert Burgee.
105. About August — one — along S. D. Highway 34, 25 miles east of Sturgis, Meade County. Observed crossing road by Wilbur Bachard. Recorded by Douglas R. West.
106. Fall — one — along Cheyenne River southeast of Eagle Butte, Dewey County. Observed in 300-acre prairie dog town by Robert Burgee.
107. October 22 — young male — 9 miles west of Onida, Sully County. Found dead on road, 4 miles from 30- to 40-acre prairie dog town by Dean Badger and Tal Lockwood. Recorded by Walter H. Kittams. Specimen 238132 (mounted), U. S. National Museum.
108. December — one — near Lodgepole, Perkins County. Found dead in trap, 10 miles from prairie dog town, by Woodrow Lewton. Recorded by Douglas R. West and Walter H. Kittams.

1961

109. March 3 — one — Sage Creek Basin, Badlands National Monument, Pennington County. Observed in small prairie dog town by Jack Close. Recorded by Robert Powell and Walter H. Kittams.
110. August — young male — along road 3 miles north of Reliance, Lyman County. Caught at night by Calvin F. Anderson. Kept at mink farm at Mitchell until February 16, 1963. Transferred to S. D. State University. Died February 2, 1964. Mounted specimen, Department of Wildlife Management.

1962

111. About 1961 — one — about 2 miles southwest of Sheep Mountain Table, Shannon County. Observed by C. M. Jurisch. Recorded by Paul F. Springer.
112. 1962 or 1963 — one — 4 miles northeast of Scenic, Pennington County. Observed in prairie dog town by Ralph Burroughs. Recorded by Paul F. Springer.
113. Summer — one — T 42 N, R 36 W, Washabaugh County. Observed catching thirteen-lined ground squirrel in alfalfa field by Loras Riggins. Recorded by Richard Adrian.
114. Summer 1962 or 1963 — one — 2½ miles south of Blunt, Hughes County. Killed in prairie dog town by son of Henry Lauing. Recorded by Donald R. Progulske and Paul F. Springer.
115. About August — one — along U. S. Highway 14, 2 miles east of Highmore, Hyde County. Observed by George M. Jonkel.

1963

116. About 1963 — one — 5 miles northwest of Mound City, Campbell County. Observed in prairie dog town by Orville Kautz. Recorded by F. Robert Henderson.
117. About 1963 — one — T 2 S, R 13 E, Pennington County. Observed by Marlow Jurisch. Recorded by Paul F. Springer.
118. March — one — near Ladner, Harding County. Observed in prairie dog town by Wesley Broer. Recorded by Donald R. Progulske.
119. Summer — one — T 39 N, R 31 W, Todd County. Observed in prairie dog town by Bryan Provancial. Recorded by Richard Adrian.

120. Summer — one — T 39 N, R 31 W, Todd County. Observed in prairie dog town (different from above) by Bryan Provancial. Recorded by Richard Adrian.

121. August 3 — skull — near Hidden Timber, Todd County. Observed in prairie dog town by John Hunter.

122. Summer — one — T 16 N, R 15 E, Perkins County. Observed chasing prairie dog by Raymond Saunders. Recorded by Douglas R. West.

123. August — one — T 40 N, R 30 W, Mellette County. Observed by H. C. Hampton. Recorded by Richard Adrian.

124. Fall — one — ½ mile south of Blunt, Hughes County. Found dead on road by A. M. Giziewski. Recorded by F. Robert Henderson.

125. September 22 — one — U. S. Highway 16, eastern Jones County. Observed in prairie dog town along road by James O. Lee, Jr.

126. Winter — one — T 15 N, R 1 E, Harding County. Found dead in trap in prairie dog town during blizzard by hired hand of Dahlen brothers. Recorded by Douglas R. West and Donald F. Fortenbery.

127. December — one — T 40 N, R 30 W, Mellette County. Shot by rabbit hunter at night. Recorded by Richard Adrian.

1964

128. 1964 — one — T 20 N, R 3 E, Harding County. Observed in prairie dog town by Joe Painter. Recorded by F. Robert Henderson.

129. May — pair — 6 miles southeast of Timber Lake, Dewey County. Observed in prairie dog town by Dallas G. Ingles.

130. Summer — one — T 43 N, R 37 W, Washabaugh County. Observed in abandoned prairie dog town by Louis Herscher. Recorded by F. Robert Henderson and Richard Adrian.

131. Summer — one — about 6 miles west of Cottonwood, Pennington County. Observed in road ditch by Frank Pratt. Recorded by F. Robert Henderson.

132. Summer — one — T 40 N, R 33 W, along Washabaugh - Mellette County line. Shot along road by Marvis Littier. Recorded by F. Robert Henderson.

133. Summer — one — T 41 N, R 37 W, Washabaugh County. Observed crossing road by Charles Vogelgesang. Recorded by F. Robert Henderson.

134. June — four to six — T 98 N, R 72 W, Gregory County. Nest of young ferrets plowed under in old corn field by Lloyd Gilbert. Recorded by Richard Adrian and F. Robert Henderson.

135. June — one — T 1 S, R 17 E, Pennington County. Observed in prairie dog town by Peder Kjerstad. Recorded by Richard Adrian and F. Robert Henderson.

136. About July 1 — one — T 13 N, R 22 E, Dewey County. Observed in small prairie dog town by Rock Cowan. Recorded by Dale Wade.

137. July — one — T 102 N, R 78 W, Tripp County. Shot in hayfield by James Calhoon. Recorded by Richard Adrian and F. Robert Henderson.

138. July — two — T 97 N, R 74 W, Tripp County. Observed in hayfield by Louis Laprather. Recorded by F. Robert Henderson and Richard Adrian.

139. July — one adult and four young — southeast of Longvalley, Washabaugh County. Observed crossing road near prairie dog town at night by Frank Schramer, Jr. Recorded by F. Robert Henderson and Richard Adrian.

140. July — one — T 40 N, R 40 W, Washabaugh County. Observed at edge of prairie dog town by Dan May. Recorded by F. Robert Henderson and Richard Adrian.

141. August — one — T 98 N, R 76 W, Tripp County. Observed near farm house by Dan McCabe. Recorded by F. Robert Henderson and Richard Adrian.

142. August — one — T 42 N, R 33 W, Mellette County. Observed crossing road at night by Burrell Phipps. Recorded by F. Robert Henderson and Richard Adrian.

143. August — four — T 20 N, R 12 E, Perkins County. Observed during haying by Mrs. Woodrow Lewton and son, 8 miles from prairie dog town. Recorded by Douglas R. West.

144. August 7 — one — T 40 N, R 31 W, Mellette County. Observed in prairie dog town at 1:30 p.m. by William Pullins and Richard Adrian. One observed previously in summer 1963 by Bryan Provancial. Recorded by Richard Adrian.

145. August 17 — one — T 40 N, R 31 W, Mellette County. Observed in prairie dog town (different from above) by Bryan Provancial. One adult and four young seen next day by Richard Adrian.

146. Fall — one — T 41 N, R 41 W, Shannon County. Found dead in trail along creek near prairie dog town by Indian. Reported by Lynn Montgomery.

147. Fall — two — along White River, 15 miles south of Kennebec, Lyman County. Came out of haystack being moved. Observed by Kenneth E. Christensen. Recorded by Walter H. Kittams.

148. September — one — T 101 N, R 78 W, Tripp County. Observed in dry lake bed by Raymond Abbey. Recorded by F. Robert Henderson and Richard Adrian.

149. September — one — T 100 N, R 78 W, Tripp County. Shot in prairie dog town by Gust Johnson. Recorded by F. Robert Henderson and Richard Adrian. Skin, S. D. State University.

150. September — one — T 99 N, R 77 W, Tripp County. Observed along creek by Ivan Fischer. Recorded by F. Robert Henderson and Richard Adrian.

151. September — one — T 3 N, R 21 E, Haakon County. Observed crossing road by R. L. McIlravy. Recorded by F. Robert Henderson and Richard Adrian.

152. September — one — 8 miles northeast of New Underwood, Meade County. Observed in prairie dog town by Marllon Carter. Recorded by F. Robert Henderson.

153. October — one — T 96 N, R 72 W, Gregory County. Observed along creek by Adolf Bruntz. Recorded by F. Robert Henderson and Richard Adrian.

154. October — one — T 42 N, R 36 W, Washabaugh County. Observed along creek by Loras Riggins. Recorded by F. Robert Henderson and Richard Adrian.

155. October 7 — male — T 41 N, R 37 W, Washabaugh County. Found shot along road near prairie dog town. Recorded by F. Robert Henderson and Richard Adrian. Specimen mounted, Badlands National Monument. Viscera, S. D. State University.

156. October 20 — one — T 40 N, R 31 W, Mellette County. Observed in prairie dog town by Richard Adrian.

157. November — one — T 104 N, R 74 W, Lyman County. Observed in chicken house by Mrs. Harry Roth. Recorded by F. Robert Henderson and Richard Adrian.

158. November 9 — one — T 2 S, R 23 E, Jackson County. Observed at dusk along creek about 1 mile from prairie dog town by A. Orville Sandall.

159. Winter — one — T 20 N, R 4 E, Harding County. Observed in prairie dog town by John Niemi. Recorded by Douglas R. West.

1965

160. 1965 — one — eastern Pennington County. Observed in prairie dog town by Carroll Knutson. Recorded by F. Robert Henderson.

161. About 1965 — one — 4 miles south of Kennebec, Lyman County. Found dead on road by Kenneth E. Christensen. Recorded by Walter H. Kittams.

162. March — one or more — T 44 N, R 33 W, Washabaugh County. Observed in prairie dog town by Art Thode. Recorded by Paul F. Springer.

163. April — one — T 2 N, R 24 E, Haakon County. Observed in old culverts in farm yard by Mrs. John Larsen. Recorded by F. Robert Henderson and Richard Adrian.

164. April — one — Wayne Everidge ranch northeast of Black Horse Butte Creek, Corson County. Observed in prairie dog town by Dallas G. Ingles.

165. April 2 — one — T 41 N, R 31 W, Mellette County. Observed in prairie dog town at 11:00 a.m. by James Carr. Recorded by F. Robert Henderson and Richard Adrian. One adult and five young observed July 12, 1966, by Conrad Hillman and James Carr.

166. April 15 — one — T 5 N, R 20 E, Haakon County. Observed in haystack by William Hespe. Recorded by F. Robert Henderson and Richard Adrian.

167. April 22 — one — T 39 N, R 30 W, Todd County. Observed in prairie dog town by Jack Knipel. Recorded by Richard Adrian.

168. Late April or early May — one — T 16 N, R 16 E, Perkins County. Observed by Kelvin Englehart. Recorded by Paul F. Springer.

169. May 1 — one — T 1 S, R 22 E, Jackson County. Observed in prairie dog town carrying snake into burrow at night by Hollis Young. Recorded by F. Robert Henderson.

170. May — one — T 42 N, R 35 W, Washabaugh County. Observed running across road from prairie dog town to alfalfa field by Stanley Barber. Recorded by F. Robert Henderson.

171. May — one — T 38 N, R 41 W, Shannon County. Observed in prairie dog town by Tony Englebert. Recorded by Richard Adrian and F. Robert Henderson.

172. Summer — one — T 17 N, R 8 E, Harding County. Observed in 160-acre prairie dog town by William Wammer. Recorded by Douglas R. West.

173. Summer — one — T 41 N, R 37 W, Washabaugh County. Observed near creek in daytime by Charles Vogelgesang. Recorded by F. Robert Henderson.

174. Summer — one — Kyle, Shannon County. Killed by Leroy Apple near his house. Recorded by F. Robert Henderson.

175. Summer — one — T 5 N, R 12 E, Meade County. Observed in 20-acre prairie dog town by Harry Snook. Recorded by Douglas R. West.

176. Summer — one — T 7 N, R 14 E, Meade County. Observed in prairie dog town by Slim Carney. Recorded by Douglas R. West.

177. Early June — one — T 39 N, R 34 W, Bennett County. Observed in prairie dog town by W. D. Good. Recorded by F. Robert Henderson and Richard Adrian.

178. June — one — T 40 N, R 33 W, Washabaugh County. Observed running under haystack by Russell Allard. Recorded by Richard Adrian.

179. Early July — eight — T 119 N, R 70 W, Faulk County. Observed in Richardson ground squirrel colony by Robert Schilder. Recorded by Paul F. Springer.

180. July — one — T 40 N, R 39 W, Washabaugh County. Observed crossing road in daytime by David Jones. Recorded by F. Robert Henderson.

181. July — one — near Crow Lake, Jerauld County. Observed in prairie dog town by C. F. Gunderson. Recorded by F. Robert Henderson.

182. Last half of July — one — T 2 S, R 5 E, Custer County, elevation 5800 - 6000 feet. Observed running along road by John Clark. Recorded by Paul F. Springer.

183. August — one — along Bull Creek, 7 miles east of Hamill, Lyman County. Observed in prairie dog town by Ralph Block.

184. August or September — one — T 10 N, R 21 E, Ziebach County. Observed in prairie dog town by Ed Bickel. Recorded by Paul F. Springer.

185. August 8 — one — T 38 N, R 47 W, Shannon County. Observed in 160-acre prairie dog town by Levi Good Voice Flute. Recorded by A. Lorin Ward.

186. August 12 — young male — T 40 N, R 32 W, Mellette County. Found dead in trap in prairie dog town by Otto Huber. Recorded by Richard Adrian. Decomposed carcass with skull, S. D. State University.

187. September 29 — adult female — T 2 N, R 19 E, Haakon County. Killed at night by domestic dog in ranch yard. Observed by Marvin Eide. Recorded by F. Robert Henderson. Skin and carcass, S. D. State University.

188. October — one — T 40 N, R 34 W, Washabaugh County. Observed crossing road at night by Joe Williams. Recorded by F. Robert Henderson.

189. October — one — T 17 N, R 19 E, Ziebach County. Observed in ravine by Ed Bickel. Recorded by Paul F. Springer.

190. October 10 — male — U. S. Highway 16, T 2 S, R 20 E, Jackson County. Found dead on road in early morning by F. Robert Henderson. Skin, S. D. State University.

191. October 21 — one — T 42 N, R 32 W, Mellette County. Observed in prairie dog town by A. Orville Sandall.

192. Winter — one — near Cherry Creek, Ziebach County. Observed in 160-acre prairie dog town by George Alfilich. Recorded by Robert Burgee.

1966

193. January — one — 2 miles southeast of Hisle, Washabaugh County. Observed in prairie dog town by Pat Weaver. Recorded by F. Robert Henderson.

194. Late winter and early spring — one — T 41 N, R 36 W, Washabaugh County. Observed several times in oats strawstack, 1 mile from prairie dog town by P. W. Kattenbach. Recorded by A. Orville Sandall and F. Robert Henderson.

195. Spring — one — T 38 N, R 47 W, Shannon County. Observed in prairie dog town at night by Russell Loud Hawk. Recorded by F. Robert Henderson.

196. March 7 or 8 — adult male — T 38 N, R 26 W, Todd County. Killed by domestic dogs. Observed by William Abbott. Recorded by F. Robert Henderson. Skeleton in F. Robert Henderson Collection.

197. March 24 — one — T 40 N, R 31 W, Mellette County. Observed in prairie dog town at 1:00 a. m. by F. Robert Henderson and Donald K. Fortenbery.

198. April 13 — one — Tuthill, Bennett County. Observed standing along road at 8:30 p.m. by Donald G. Young.

199. May — one — T 19 N, R 15 E, Perkins County. Observed in prairie dog town by Constant Schell. Recorded by Douglas R. West.

200. May — one — T 3 S, R 31 E, Jones County. Killed by domestic dog. Observed near prairie dog town by Herman Hendrick. Recorded by F. Robert Henderson.

201. May 2 — two — T 43 N, R 32 W, Mellette County. Observed in prairie dog town between 2:30 and 6:40 a.m. by Conrad Hillman.

202. Summer — one — T 7 N, R 20 E, Haakon County. Observed in prairie dog town by Emery Markwed. Recorded by F. Robert Henderson.

203. Summer — two — T 40 N, R 30 W, Mellette County. Observed in prairie dog town by Richard Adrian.

204. September 12 — young female — White River, Mellette County. Shot and given to William Pullins. Specimen 289498, U. S. National Museum. Carcass, S. D. State University.

205. September 19 — one — White River, Mellette County. Observed running under a porch by Buddy Hutchinson. Recorded by William Pullins.

206. October — one — T 42 N, R 32 W, Mellette County. Observed in prairie dog town by school teacher. Observed October 7 by Conrad Hillman.

207. October 11 — one — T 42 N, R 30 W, Mellette County. Observed in prairie dog town by William Pullins.

208. October 21 — one — T 42 N, R 32 W, Mellette County. Observed in prairie dog town by A. Orville Sandall.

209. Late fall — one — northwest of Milesville, Haakon County. Observed along a creek by Donald Loobey. Recorded by F. Robert Henderson.

1967

210. Spring — one — T 2 N, R 25 E, Haakon County. Observed several times in prairie dog town by William Donovan. Recorded by F. Robert Henderson.

211. March 9 — one — T 40 N, R 34 W, Washabaugh County. Observed in prairie dog town at 7.30 a.m. by F. Robert Henderson.

212. April 29 — adult female — U. S. Highway 18, T 37 N, R 39 W, Bennett County. Found dead on road at 2:00 a.m., 3 miles from prairie dog town by Jasper Milk. Recovered by F. Robert Henderson. Mounted specimen, Pine Ridge Indian Reservation, Pine Ridge, S. D. Carcass with skull, S. D. State University.

213. May — one — T 3 S, R 15 E, Pennington County. Observed along road 1 mile from prairie dog town by Louis Blumer. Recorded by Donald K. Fortenbery.

214. May 9 — one — T 42 N, R 30 W, Mellette County. Observed crossing road at 9:30 p.m. by Mrs. James Carr.

215. May 16 — adult female — U. S. Highway 83, T 3 S, R 29 E, Jones County. Chased by great horned owl onto road adjacent to prairie dog town and run over by Dale Richardson at 3:00 a.m. Recorded by F. Robert Henderson. Mounted specimen, S. D. Department Game, Fish and Parks. Carcass with skull, S. D. State University.

216. May 17 — one — T 41 N, R 30 W, Mellette County. Observed in prairie dog town at 12:10 a.m. by Conrad Hillman.

217. Summer — one — 5 miles north of Sharps Corner, Shannon County. Observed by Bill Lone Bear. Recorded by F. Robert Henderson.

218. Summer — one — T 36 N, R 45 W, Shannon County. Observed by George Swift Bird. Recorded by F. Robert Henderson.

219. June 29 — one — T 42 N, R 40 W, Washabaugh County. Observed crossing road near prairie dog town at 9:00 p.m. by F. Robert Henderson, Thomas Kuck, and David Linde.

220. July or August — two — along U. S. Highway 212, 5 miles east of Faith, Ziebach County. Observed by Mrs. Dono Capp. Recorded by Douglas R. West.

221. July 7 — one — T 124 N, R 78 W, Walworth County. Observed in 25-acre prairie dog town by Walter Larsen.

222. July 18 — one — Interstate 90, 1 mile east of New Underwood, Pennington County. Observed crossing road by Jack Hansen. Recorded by B. J. Rose.

223. August 2 — adult and four young — 1 mile southwest of White River, Mellette County. Observed in 10-acre prairie dog town by Raymond L. Linder and Donald K. Fortenbery.

224. September 5 — young male — on S. D. Highway 40, 3 miles west of White River, Mellette County. Run over on road by Jerry Krogman. Recorded by Conrad Hillman. Specimen at S. D. State University.

225. Late November — one — T 19 N, R 1 E, Harding County. Observed in prairie dog town by Lowell Cordell. Recorded by Paul F. Springer.

SCIENTIFIC NAMES OF ANIMALS AND PLANTS

MAMMALS

Badger **(Taxidea taxus)**
Bison **(Bison bison)**
Black-footed ferret **(Mustela nigripes)**
Black-tailed prairie dog **(Cynomys ludovicianus)**
Bobcat **(Lynx rufus)**
Coyote **(Canis latrans)**
Desert cottontail **(Sylvilagus auduboni)**
Domestic cat **(Felis catus)**
Domestic dog **(Canis familiaris)**
European fitch ferret or European polecat **(Mustela putorius)**
Golden-mantled squirrel **(Citellus lateralis)**
Long-tailed weasel **(Mustela frenata)**
Mink **(Mustela vison)**
Pronghorn **(Antilocapra americana)**
Richardson ground squirrel **(Citellus richardsoni)**
River otter **(Lutra canadensis)**
Short-tailed weasel **(Mustela erminea)**
Striped skunk **(Mephitis mephitis)**
Thirteen-lined ground squirrel **(Citellus tridecemlineatus)**
White-tailed jackrabbit **(Lepus townsendi)**
White-tailed prairie dog **(Cynomys gunnisoni)**

BIRDS

Burrowing owl **(Speotyto cunicularia)**
Golden eagle **(Aquila chrysaetos)**
Great horned owl **(Bubo virginianus)**
Horned lark **(Eremophila alpestris)**
Killdeer **(Charadrius vociferus)**
Rough-legged hawk **(Buteo lagopus)**
Snowy owl **(Nyctea scandiaca)**
Western meadowlark **(Sturnella neglecta)**

REPTILES

Bull snake **(Pituophis melanoleucus)**
Prairie rattlesnake **(Crotalus viridis)**

INSECTS

Carolina locust **(Dissosteira carolina)**
Prairie dog flea **(Opisocrostis hirsutus)**

PLANTS

Blue grama **(Bouteloua gracilis)**
Buffalo grass **(Buchloe dactyloides)**
Green needlegrass **(Stipa viridula)**
Western wheatgrass **(Agropyron Smithii)**

Prairie Dog Distribution in Areas Inhabited by Black-footed Ferrets

ABSTRACT: The distribution of black-tailed prairie dog *(Cynomys ludovicianus)* towns was delineated in a 1490 km^2 study area in Mellette County, South Dakota, and was examined to determine the characteristics of black-footed ferret *(Mustela nigripes)* habitat. Between 1964 and 1974, black-footed ferrets were observed on 14 prairie dog towns in this area. Eighty-six prairie dog towns, located throughout the study area, were not randomly distributed; towns were paired or clumped in spatial distribution. Mean distance between a town and its nearest neighbor was 2.4 km; mean distance between a ferret-occupied town and the nearest town was similar, 2.7 km. Management recommendations are to maintain at least eight towns per township, each at least 12 ha in size. Of these eight towns, two or more should exceed 40 ha.

INTRODUCTION

The black-footed ferret, an endangered species, has been the subject of intensive study in Mellette Co., South Dakota, since the discovery of a family group there in 1964 (Hillman, 1968; Henderson *et al.,* 1969; Sheets *et al.,* 1972; Linder *et al.,* 1972; Hillman and Linder, 1973). Ferrets observed during those studies inhabited 14 black-tailed prairie dog towns. No ferrets were observed off towns with the exception of those killed on roads, killed by dogs or shot. Ferrets were seen away from prairie dog towns by ranchers and other local people, but none of these reports was verified.

Black-footed ferrets feed mainly on prairie dogs; they utilize prairie dog burrows for denning sites and shelter, and remain on the same prairie dog town for indefinite periods of time (Hillman, 1968; Sheets *et al.,* 1972). Ferrets were observed on prairie dog towns in Mellette County each year from 1964 to 1974, but population censuses were impossible because of the ferret's nocturnal and secretive habits.

The purpose of this paper is to describe characteristics and spatial distribution of prairie dog towns in ferret-occupied areas. This information may be helpful to land managers attempting to preserve prairie dog towns as ferret habitat.

METHODS AND STUDY AREA

Prairie dog towns (located by aerial surveys, interviews with landowners and examination of U.S. Soil Conservation Service aerial photos) were plotted on topographic and county maps. Surveys to locate ferrets were conducted periodically on prairie dog towns by methods previously described by Henderson *et al.* (1969) and Hillman (1968). Only those ferrets actually sighted were included.

The 1490 km^2 study area in western Mellette Co., South Dakota, is within the White River drainage basin (Fig. 1). Topography consists of rolling grasslands interspersed with small creeks, brushy draws and river breaks; badlands occur in the western part. Eighty-two percent of the land area in the county is rangeland; cattle ranching is the primary enterprise (White, 1975).

Soils in the area are from the Norrest, Huggins-Kadoka, Imlay-Conata-Badlands, and Opal-Promise-Samsil associations; they are derived from clayey shales of the Pierre formation (White, 1975). The climate is characterized by hot summers and cold winters. Mean annual temperature is 8 C, and average annual precipitation is 43 cm, 75% of which occurs during April through September (Westin *et al.,* 1959).

Prairie dog towns were chiefly on lands owned or leased by operators of large ranches. In most instances, ranchers were tolerant of prairie dogs if their numbers were not allowed to increase. Several landowners were sympathetic toward this study and withheld treatment of towns that were inhabited by ferrets. Approximately 40% of the towns were on Indian lands. The Rosebud Sioux Tribe has not had an active prairie dog control program in the area since 1965.

RESULTS AND DISCUSSION

From 1966 to 1973 prairie dog control programs were limited, a few new prairie dog towns appeared, and expansion of towns was not extensive. Seven towns (146 ha) were treated under government-supervised programs in 1966-1969, but the only control in 1970-1973 was practiced by landowners. Extensive ferret surveys were conducted in the study area during this period (Hillman and Linder, 1973). Since 1973, prairie dog towns have expanded, but no accurate count of new towns or towns poisoned by landowners has been possible. This information also was lacking for years prior to 1966.

Eighty-six prairie dog towns were located and mapped (Fig. 1) on four topographic sites. Towns ranged in size from 2-120 ha. Thirty towns (35%) were on benches or terraces adjacent to a creek or floodplain, 30 towns (35%) occurred in rolling hills of slope greater than 5%, 20 (23%) were on "flats" and six towns (7%) were in badland areas. Occasionally, larger towns occurred on a combination of two topographic situations.

Prairie dog towns commonly occurred near rivers or creeks throughout western South Dakota and much of the Great Plains region (Koford, 1958). In 1974, 83 towns occurred on a strip 1-6 km wide along 160 km of the White River in Shannon Co., South Dakota. Towns were also numerous near the Cheyenne and Belle Fourche rivers and their tributaries. River or creek bottom sites in Mellette County are characterized by deep, fine-to-medium-textured alluvial soils. Trees and small shrubs are common on floodplains. Prairie dogs occupied benches which rarely exceeded a 5% slope. They occupied lower lands in level, unwooded oxbows along major drainages with wide floodplains. These sites were subject to occasional flooding.

Prairie dog towns also were common in draws or swales in rolling grasslands. Nine of 30 towns in this type occurred in the upper end or grassy bowls of minor tributaries. Other grassland towns occurred in shallow depressions, gently rolling hills or on hillsides. Many towns were associated with abandoned farm buildings, windmills and stock ponds.

Twenty towns occurred on relatively flat land in lowlands or on high prairie terraces. Panspots or alkaline areas frequently were inhabited by prairie dogs on the lowlands. Prairie dogs occupied high, prairie terraces which previously were farmed; several of these towns were poisoned and plowed since 1973.

Six prairie dog towns occurred in badland areas. They occupied grassy plateaus adjacent to or between deep, dry creekbeds. Two towns occurred in shallow, dense-clay sites formed from erosion of adjacent badland buttes. Steep-sided, barren outcroppings limited the expansion of most badland towns; generally, badlands are unsuitable for prairie dogs.

Several large tracts of rough terrain, steep canyons and river breaks within the study area were not occupied by prairie dogs. Throughout the study area, towns were repeatedly poisoned in past years, and many were not reoccupied.

Black-footed ferrets occupied 14 towns in the four sites in relative proportion to the number of towns that occurred in each type; four were near creeks, five in rolling grasslands, four were on flatland and one was in a badland area.

Unlike some members of the weasel family, ferrets are believed to kill only enough to eat. A town (14 ha) occupied by ca. 52 prairie dogs in June 1966 was occupied by a single ferret for

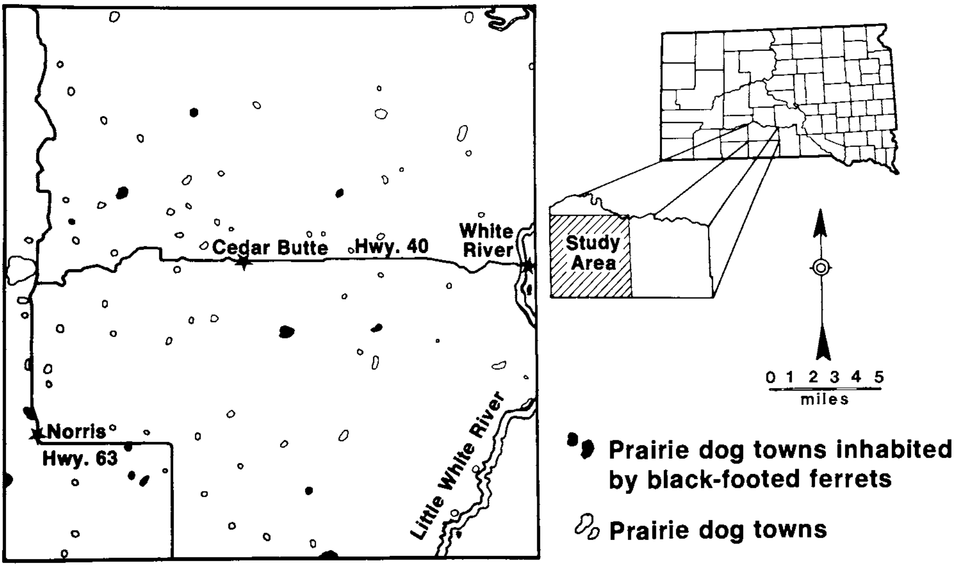

Fig. 1.—Black-footed ferret study area in western Mellette Co., South Dakota

6 months, but prairie dog numbers were not severely reduced. By autumn 1967 prairie dogs were more abundant than in 1966 on that town (Hillman, 1968). Prairie dog numbers were not markedly reduced on 12 other towns inhabited by one or two ferrets for portions of a year.

The larger towns may be more important for adult female ferrets rearing young. Of 11 litters observed, six occurred on four towns that equaled or exceeded 40 ha (40, 43, 57 and 120 ha). These towns were considerably larger than the average of 8 ha as recorded for 151 towns throughout Mellette County (Linder *et al.,* 1972). The sizes of towns occupied by the other five litters were 10, 12, 13, 13 and 16 ha, all larger than average. Obviously, a greater food supply is required for a family group of ferrets. Numbers of prairie dogs declined on portions of one town frequented by ferrets, but, generally, total numbers of prairie dogs were not greatly reduced on towns occupied by litters (Hillman and Linder, 1973).

We used procedures for demonstrating the occurrence of nonrandom distribution in populations given by Clark and Evans (1954). Although prairie dog towns occurred throughout the study area, they were not randomly distributed. The spatial relationship was a clumped or paired distribution.

The mean distance between a town and its nearest neighboring town was 2.4 km; the distance between a town occupied by ferrets and its nearest neighboring town (2.7 km) was similar. Mean numbers of towns per km^2 that occurred in 1.6-km-wide bands (mile-wide bands) away from towns occupied by ferrets were 0.47, 0.37, 0.45 and 0.29; these were not different ($P>0.05$). The mean distance between towns inhabited by ferrets was 5.4 km (range 1.0-11.1).

Prairie dogs are now more abundant in Mellette County than 6 years ago, but ferret observations have not increased proportionally. Prairie dogs also are more abundant in other areas of South Dakota, yet ferrets have not been seen in these areas in recent years.

Because of the limited understanding of ferret habitat needs, the following recommendations should be interpreted as meeting only minimal habitat requirements: (1) maintain at least eight towns per township; (2) each town should be at least 12 ha in size; and (3) two or more towns should exceed 40 ha. These recommendations are based on data from our study area, where ferrets have been known to survive over a period of years.

Acknowledgments.—Funds for this study were supplied by the U.S. Fish and Wildlife Service. Both the South Dakota and Iowa Cooperative Wildlife Research Units are jointly supported by the U.S. Fish and Wildlife Service and the Wildlife Management Institute. For the South Dakota Unit, the Department of Game, Fish and Parks and South Dakota State University join in support, and for Iowa, the State Conservation Commission and Iowa State University join in support.

Abstract

Historically, the plains bison (*Bison bison* Linnaeus) was the most numerous and influential grazer on the Great Plains. Today 500 000 bison occupy North America among more than 100 000 000 cattle. In an attempt to restore their historical ecological role, bison are translocated onto landscapes previously manipulated for cattle use through water and fence development. We hypothesized that bison would use these landscapes similarly to cattle, thus maintaining homogenous grazing and reducing the restoration potential of bison at a landscape scale. We quantified differences between bison populations at different locations and spatial scales (American Prairie Reserve, Malta, Montana, USA, and Grasslands National Park, Val Marie, Saskatchewan, Canada, 2010–2011) and bison and cattle at similar locations and spatial scales using behavioral observations, movement analyses, and resource selection functions. Bison and cattle differed in all behaviors (grazing, standing, bedded, moving, other); however, landscape attributes resulted in behavior differences within species. Cattle spent a higher proportion of time grazing (45–49%) than bison (26–28%) and increased time at water. Bison moved at a 50–99% faster rate than cattle, and first passage time movement analyses identified selection of bison foraging patches (11 690 ha) larger than cattle foraging patches (48–615 ha). Similar to cattle, bison avoided most vegetation communities in relation to riparian communities and selected areas closer to water. Cattle selected for high plant biomass, whereas bison selected for intermediate plant biomass. This study has implications when bison and cattle are used to meet prairie restoration objectives. For bison, large landscapes that include variation in topography and vegetation communities are required. Furthermore, limiting manmade water sources may facilitate bison grazing patterns that more closely approximate historical bison use. For livestock, reduced movement and increased time spent grazing encourage grazing practices that increase heterogeneous grazing at a pasture scale.

Key Words: behavior, first-passage time, grazing, heterogeneity, resource selection, water

INTRODUCTION

The near extinction and subsequent recovery of plains bison (*Bison bison* Linnaeus) throughout North America was the first and greatest conservation success in North America (Sanderson et al. 2008). Today ~500 000 bison occupy North America because of the cooperation of private individuals, nonprofit organizations, and the federal governments of the United States, Canada, and Mexico. Despite the numerical recovery of the species, recent questions have surfaced regarding the ecological success of these efforts because fewer than 21 000 plains bison are managed as conservation herds (i.e., not for commercial use; $n=62$). Thirteen percent ($n=8$) of conservation herds are outside of their historical range, 92% ($n=57$) have fewer than 1 000 individuals, and only 8% ($n=5$) are managed on areas of more than 2 000 km^2 (Gates et al. 2010). In comparison, more than 95% of bison are in commercial production and are subjected to animal husbandry practices (e.g., altered sex:age ratios, unnatural growth performance, reduced mate competition), which may result in irreversible changes to morphology, physiology, and behaviors (Freese et al. 2007) that alter their ecological influence on the landscape. The collective effect of ecological alterations and issues such as disease (Aune and Gates 2010) and domestic cattle gene introgression (Halbert and Derr 2007) can prohibit the mixing of commercial and conservation herds because of different management and conservation goals. As a result, many conservation groups and state and federal agencies are questioning the ecological significance of replacing historic bison populations with domestic cattle at a landscape scale.

Historically, bison were the dominant grazer throughout the Great Plains, affecting vegetation communities through grazing, physical disturbance, nutrient cycling, and seed dispersal (McHugh 1958; Knapp et al. 1999). These activities contributed to grassland heterogeneity that supported many prairie obligate species (e.g., grassland songbirds) in the tall, mixed, and short grass prairie (Fuhlendorf et al. 2006; Powell 2006; Gates et al. 2010). Following the reduction of the bison herds, bison were replaced by domestic cattle, and a significant shift occurred, resulting in overgrazing and then rotational grazing regimes. Contemporary range management practices are

Manuscript received 28 August 2012; manuscript accepted 13 August 2013.

designed to maximize livestock production through cross-fencing and uniformly distributed stock reservoirs, effectively rescaling the grazing process across the landscape in a homogenous fashion (Fuhlendorf and Engle 2001; Derner et al. 2009).

Today livestock numbers on rangelands in the United States and Canada are two times higher than historical bison estimates,[1] yet there are few studies comparing the ecological similarities between introduced livestock and bison, particularly when managed as wild populations on large, complex landscapes (Fuhlendorf et al. 2010). Bison and cattle demonstrate fundamental ecological differences in habitat use (van Vuren 1983; Allred et al. 2011), forage use (Peden et al. 1974; Plumb and Dodd 1993; Towne et al. 2005), and behavior (Plumb and Dodd 1993). In addition, water requirements have been identified as a major difference between the species as cattle spend more time near water resources and riparian areas than bison (van Vuren 1983; Fuhlendorf et al. 2010). In particular, bison employ distinct travel patterns that include travel from general use areas (e.g., feeding, bedding) to watering areas where they spend minimal time and then return to general use areas (McHugh 1958; van Vuren 1979). However, only Allred et al. (2011) have explicitly tested for cattle selection and bison avoidance of riparian areas and water sources at a large spatial scale.

Data are available regarding the ecological differences between bison and cattle; however, direct comparisons between bison and cattle are difficult because of varying management practices (e.g., pasture size, stocking densities, management priorities, cattle breed) and confounding environmental factors (Plumb and Dodd 1993; Towne et al. 2005; Fuhlendorf et al. 2010). Fuhlendorf et al. (2010) reported nine studies that compared bison and cattle with an ecological focus, only two of which attempted to control for confounding effects. Recent work on the Tallgrass Prairie Reserve was the third study to control for confounding effects and the first to occur on pasture units over 300 ha (Allred et al. 2011).

Bison translocation efforts are occurring in the Northern Great Plains in areas previously manipulated for livestock (i.e., water development and fence construction). Because these translocation efforts are implemented beside domestic livestock operations, we were provided opportunities for side-by-side comparisons of bison and cattle. Furthermore, with multiple bison populations within the region, we were able to compare pasture attributes used by bison across differing vegetation communities and spatial scales. Thus, our objectives were to compare the behavior, movement, and resource use of bison and cattle on large pasture units ($> 1\,000$ ha) within the Northern Great Plains in an effort to make inferences regarding potential impacts on landscape heterogeneity. For this study, landscape hetero- and homogeneity refers to vegetation structure and composition at spatial scales of more than 1 000 km^2. Pasture attributes refer to topographic characteristics, vegetation communities, and management practices. We hypothesized that pasture attributes would influence the behaviors (e.g., standing, bedded, grazing, movement, and resource use) of bison and cattle. As such, we predicted bison and cattle in units with similar pasture attributes would demonstrate comparable behaviors reported in previous studies of smaller pasture units. We also predicted bison would differ in their ecological behaviors (e.g., movement, water use) when under different management structures, including pasture size and water density.

METHODS

Study Area

We compared bison and cattle in two study areas within the northwestern glaciated plain ecoregion (Forrest et al. 2004) of north-central Montana and southwestern Saskatchewan, Canada, in 2010 and 2011 (Fig. 1). In north-central Montana, we compared bison on the American Prairie Reserve (APR [67% public land]) and cattle on the Barnard Ranch (BR [65% public land]) and Weiderrick Ranch (WR [100% public land]). The APR (lat 47°45′48″N, long 107°41′43″W) is located 74 km south of Malta, Montana, and is adjoined on the east by BR (lat 47°43′00″N, long 107°38′00″W) and west by WR (lat 47°44′11″N, long 107°51′28″W). To compare bison across spatial scales, vegetation communities, and water availability, a second bison site was selected 150 km north in Grasslands National Park (GNP [Val Marie, Saskatchewan, Canada {lat 49°09′40″N, long 107°32′49″W}]).

Dominant plant species on APR, BR, and WR are representative of a sagebrush steppe system that includes blue grama (*Bouteloua gracilis* Griffiths), needlegrass (*Stipa* spp. Beauv), crested wheatgrass (*Agropyron cristatum* Gaertn), silver sagebrush (*Artemisia cana* Pursch), and Wyoming big sagebrush (*Artemisia tridentata* Nutt). Sedges (*Carex* spp.), cacti, and forb species are also common in the area. Dominant plant species in GNP are representative of the mixed-grass prairie ecosystems and include blue grama, needlegrass, western wheatgrass (*Pascopyrum smithii* Á Löve), and silver sagebrush.

Large ungulates on all sites include mule deer (*Odocoileus hemionus* Rafinesque), white-tail deer (*O. virginianus* Zimmermann), and pronghorn (*Antilocapra americana* Ord). Elk (*Cervus elaphus* Linnaeus) are common on all sites except GNP. Black-tailed prairie dogs (*Cynomys ludovicianus* Ord) and coyotes (*Canis latrans* Say) are common in all areas. Greater sage grouse (*Centrocercus urophasianus* Bonaparte), Baird's sparrows (*Ammodramus bairdii* Audubon), and mountain plover (*Charadrius montanus* Townsend) are grassland bird species of conservation concern found throughout the region.

The APR, BR, and WR lie in a semiarid region consisting of upland flats intersected by coulees and ephemeral streams flowing toward the Missouri River. Yearly precipitation ranges from 25.4–27.9 cm; however, 2010 and 2011 were 1.5–2.0 greater than the annual average (45.6 and 57.1 cm, respectively). Mean annual temperature is 6.5°C and ranges from –8.4°C in January to 20.8°C in July. Elevation ranges from 700 to 825 m. Soil primarily contains heavy clay loams with moderate amounts of salt resulting in high impermeability by water. Thus, most water developments remain full throughout the year.

The GNP also lies in a semiarid region and consists of similar topographic features as listed above. The Frenchman River

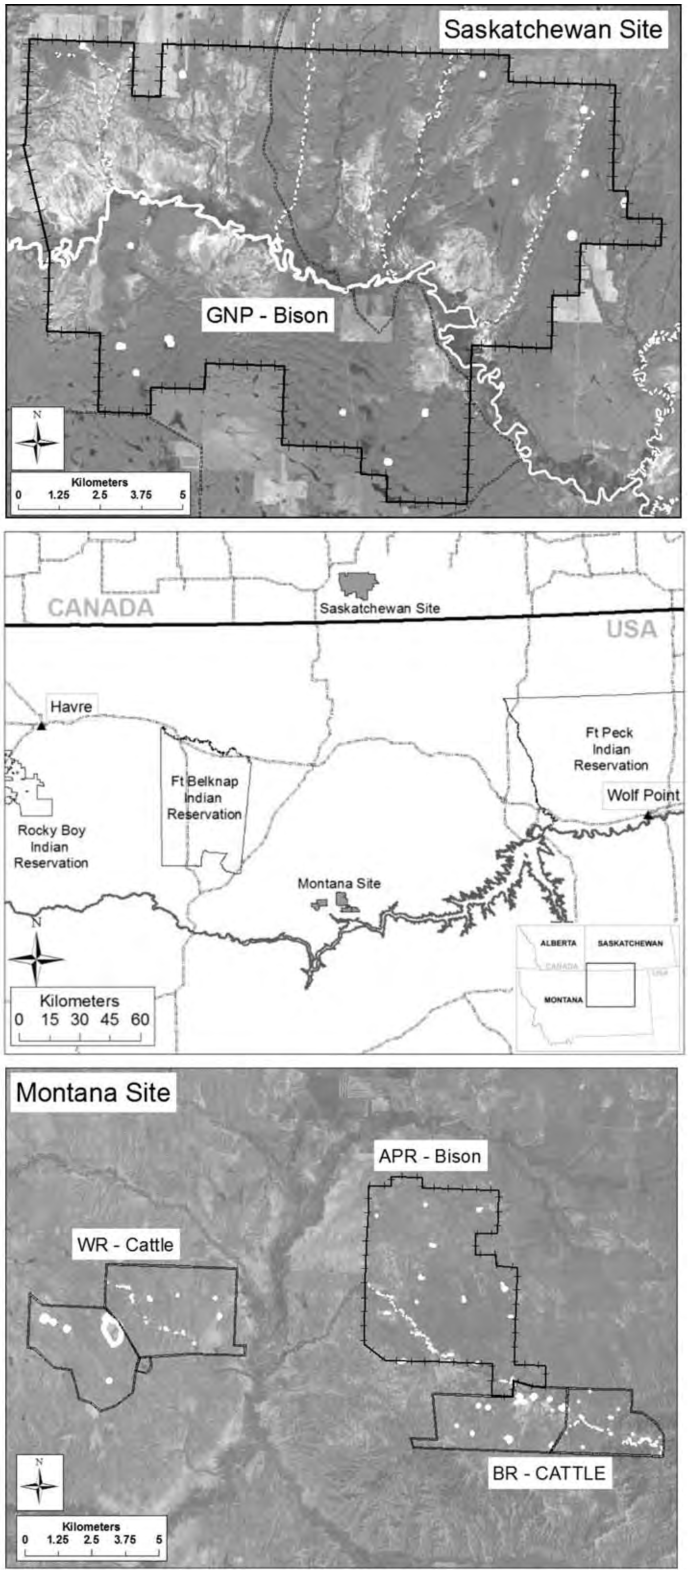

Figure 1. Location of bison and cattle study sites. Bison herds were located at American Prairie Reserve (APR; diamond) and Grasslands National Park (GNP; star). Two cattle herds are located in pastures adjacent to APR bison herd. White identifies man-made stock reservoirs and remnant pools within ephemeral streams. Dashed line identifies main ecotour route through GNP. Sites at APR are located 74 km south of Malta, MT, USA, and GNP is located 20 km southeast of Val Marie, SK, Canada.

runs through the southern section of the park with consistent, regulated flow throughout the year. Annual precipitation ranges from 30 to 33 cm; however, 2010 and 2011 were 1.4–2.0 times greater than average (46.5 and 53.1 cm, respectively). Mean annual temperature is 3.4°C and ranges from –13.4°C in January to 18.8°C in July. Elevation ranges from 750 to 900 m.

Bison on APR ($n=147$ in and 215 in 2010 and 2011, respectively) were contained within a 3 555 ha electrified pasture unit from 1 May through 31 October of each year (Fig. 1). The pasture contains 15 manmade reservoirs and an ephemeral stream that maintained small remnant pools during the study. Reynolds Hill Road passes through the eastern section of the APR, receiving low to moderate levels (~ 30 vehicles $\cdot$ d^{-1}) of use throughout the summer with heavier use (~ 250 vehicles $\cdot$ d^{-1}) during hunting season (1 September–25 November). Bison on GNP ($n=147$ and 195 in 2010 and 2011, respectively) were contained within an 18 153 ha pasture unit containing 26 reservoirs (Fig. 1); however, bison typically used only the northeast portion of the park during summer ($\sim 4\,200$ ha). This summer area contained five manmade reservoirs (three of which were permanent throughout summer), one large depression, and three ephemeral channels that contained remnant pools during the study. In addition to reservoirs, the Frenchman River provides water throughout the year, except when frozen. The main ecotour road passes through the center of the park ($\sim 6\,000$ visitors $\cdot$ yr^{-1}) from north to south and receives low to moderate levels of use throughout the summer, but recreational use is rare in the core summer range.

The WR grazed 100 cow/calf pairs (red and black Angus) from 1 July to 15 October on 2 rotational pastures (1 090 and 1 408 ha), that contained 5 to 7 reservoirs per pasture (Fig. 1). The BR grazed ~ 140 cow/calf pairs (Hereford and red Angus) on two rotational pastures (777 and 1 000 ha) that contained 6–8 reservoirs per pasture. The west BR pasture was bisected by Reynolds Hill Road. Stocking density was similar across APR and WR cattle pasture units but differed from BR pasture units (Table 1).

GPS Data Collection

We deployed Global Positioning System (GPS) radiocollars (Lotek 3300, Lotek 4400, Lotek Wireless Fish and Wildlife Monitoring, Newmarket, Ontario, Canada and NSG-LD2, North Star Science and Technology, LLC, King George, Virginia, USA) on adult female bison and cattle.[2] Bison were immobilized (A3080 and Xylazine; reversed with Naltrexone, or a mixture of Butorphanol-Azaperone-Medetomidine [BAM]; reversed with Naltrexone, Atipamezole and Tolazine, K. Kunkel, American Prairie Reserve, personal communication) by air-powered darts (Pneu-Dart, Williamsport, PA) fired from the ground. Cattle were physically restrained in a squeeze chute. Sixteen animals were instrumented in the study ($n=2$ on APR, $n=4$ on GNP, $n=5$ on BR, $n=5$ on WR), of which five individuals remained collared throughout the duration of the study ($n=2$ on APR, $n=3$ on GNP). Collars were scheduled to obtain locations every 1, 2, or 3 hr from collar deployment (1 June–9 July) till 31 August (or until collar failure) in 2010 and 2011.[3] The GPS locations were

censored from analysis when APR bison moved outside of the designated pasture unit. This research was approved by the University of Montana Animal Care and Use Board (Animal Use Protocol No. 014-10PKWB) and Parks Canada (Permit No. GRA-2010-5415).

Landscape Variables

Abiotic variables (e.g., aspect, slope, and elevation) were developed from the 30×30 m Montana Digital Elevation Model and 15×15 m Canadian Digital Elevation Model. Biotic variables included vegetation community and 250×250 m Normalized Difference Vegetation Index data (NDVI [Moderate Resolution Imagine Spectroradiometer {Huete et al. 2002}]). Vegetation classifications on GNP were based on field work completed by ground sampling (R. Sissons, GNP, unpublished data). Landcover type was classified on APR, BR, and WR using remotely sensed data and was designed to allow for comparison between vegetation communities on GNP. We delineated 10 vegetation communities (eroded, upland grassland, disturbed, sloped grassland, riparian, valley grassland, treed, unclassified, sage-brush, and water bodies).[4] We used a dynamic measure of vegetation productivity by estimating primary productivity from midmonth NDVI estimates (Tucker and Sellers 1986). We analyzed anthropogenic variables using Euclidean distance estimates (km) for fence, water, and roads. We located permanent water sources using BLM (Malta Field Office, Malta, MT, USA) and Parks Canada (GNP Headquarters, Val Marie, Canada) topographic maps. We inspected water developments monthly to confirm water availability throughout summer. Additional water sources (e.g., hardpans, rainfall, drainages) are ephemeral pools (< 1 wk); thus we assumed they were homogenous throughout the pasture units and did not influence overall movement patterns of bison and cattle relative to permanent water sources.

Behavior

We conducted behavior observations of bison and cattle near semipermanent (< 3 mo) to permanent water sources to quantify the use of water by both species, and thus relate resource selection (see below) to water requirements. The distinct differences in use of watering areas by bison and cattle (van Vuren 1983; Fuhlendorf et al. 2010) allowed for inferences on the impact of variable water densities on landscape use by bison and the overall requirement of water by bison relative to cattle. Thus, we predicted time spent watering would differ between species (i.e., cattle > bison). We also predicted differences in time spent watering across bison sites (i.e., GNP > APR) due to GNP's decreased water availability in the northeast corner of the park, thus imitating a more historical water density.

Opportunistic behavioral observations were also recorded when groups of individuals were ≥ 25 m from water (25–1027 m). We assumed that at distances over 25 m, animals had not watered recently, and thus would make directed movements when watering was required. Observations (≤ 4 hr) occurred during daylight hours twice per day for one week per month per study group from 22 May–23 August 2010 and 2011. We were unable to collect observation data and watering events for 1.5 mo on the BR in 2010 due to the grazing rotation schedule and access was limited to WR in 2010 and 2011 due to weather conditions. This resulted in 87 behavioral observations ($n=34$ on APR, $n=29$ on GNP, $n=18$ on BR, $n=6$ on WR) spanning 155.3 hr and 544 watering events (i.e., the start of an adult animal drinking water), across all study areas ($n=200$ on APR, $n=185$ on GNP, $n=119$ on BR, $n=40$ on WR). Prewatering behavior of mixed groups (female, calf, and subadult males) was determined using instantaneous scan sampling (Altmann 1974) from distances over 100 m (Komers et al. 1992) and pooled across individuals within the sampling unit. A sampling unit consisted of a group of more than 2 animals separated from other groups by more than 100 m (range=2–224; median=38 [Fortin et al. 2003]) with multiple groups being observed concurrently if visible. Prior to watering events, behavior (grazing, standing, bedded, moving, other) of all individuals was recorded at 15 min intervals (Plumb and Dodd 1993). During the observation periods, individuals were also observed continuously for instances of watering events. When an individual animal began watering, the observation period (instantaneous scan samples) for all individuals ceased, and weather data (temperature, cloud cover, wind speed) and time spent at water (i.e., time in minutes from initial drinking activity to time when animal was more than one body length from water source) for each watering individual was recorded.

We calculated proportional differences in ecologically significant behaviors (i.e. moving, grazing). We used a χ^2 test to quantify whether behaviors differed among and within species. We used ANOVA to compare time spent at water between species and study locations. Lastly, a multiple analysis of variance (MANOVA) was used to calculate the influence of temperature on time spent at water. Statistical

analyses were conducted using the Rcmdr package in R 2.15.1 (Fox 2005).

Movement

We predicted bison movement rates (MR), calculated from GPS data as distance (d) in meters (step length) divided by time (t) in seconds (fix interval), would be larger than those of cattle on pasture units of similar attributes due to increased resource (i.e., water) requirements by cattle. This would be expected if cattle were unable to travel large distances from water when physiologically constrained by higher summer temperatures and, thus, resulting in circular movements within a given radius of a watering source. In contrast, we expected bison to make linear movements away from water sources, which would result in greater movement rates. We also predicted bison on APR would demonstrate slower MR than bison on GNP due to reduced pasture units (i.e., fence construction). This would be expected if long-distance movements were inhibited by fence construction, thus decreasing the total distance traveled relative to a fix-interval. Movement rates had a non-normal distribution; thus we used a negative binomial regression to test this hypothesis. Analyses were performed in R 2.15.1 using the MASS package (Venables and Ripley 2002).

We used the first passage time (FPT) analyses to measure the search effort along a pathway (Fauchald and Tveraa 2003) to identify the spatiotemporal scale of biologically relevant movements (Turchin 1998; Morales et al. 2005). Specifically, FPT incorporates step length, turning angles, and tortuosity (Fauchald and Tveraa 2003) to estimate the spatial scale at which the consumer perceives a resource. Variance in FPT, calculated by the time it takes an animal to travel across a circle of a specified radius (Fauchald and Tveraa 2003), allows ecologists to distinguish area-restricted search behaviors from movement behaviors between patches.

FPT analyses were conducted in the adehabitatLT package of R 2.15.1 (Calenge 2006). Circles of radii between 50 and 15 000 m, increasing at 25 m increments, were applied to each GPS location along an individual movement path for bison and cattle. Location data were used from the focal sampling period (June–August 2010 and 2011) except for APR bison in 2011. The omission of 2011 data for APR bison was due to temporary bison movements outside of the designated pasture unit, which necessitated data censoring and resulted in an inadequate sample size for FPT analysis. For each GPS location along an individual movement path, we calculated the time spent moving along the path within a circle of a given radius. Where those circles intersected the movement path, we determined passage time of the resulting segment assuming constant rates of travel along interlocation steps. First passage times were not calculated in instances of missed locations which created breaks along the path (Williams et al. 2012). We evaluated the variation in passage time along each movement path using circles with radii ranging from 50 to 15 000 m at 25 m increments. Variation in FPT at each scale (circle radius) indicates the degree that movements are aggregated along the path. Because variation in FPT is expected to increase with increasing circle radii, variance in FPT was divided by the area of the circle (Frair et al. 2005; Williams et al. 2012) as a function of scale (circle radii), thus providing an indicator of the landscape scales to which individuals are responding for the summers of 2010 and 2011.

Resource Selection

We used a resource selection function (RSF) framework to compare resource use of bison and cattle during summer (1 June–31 August; Manly et al. 2002). Our specified covariates were vegetation community, water availability, and additional abiotic (elevation, aspect, slope), biotic (NDVI), and anthropogenic covariates (distance to roads, distance to fence) identified in previous bison and cattle resource selection studies. Because RSFs assume independence among observations (Hosmer and Lemeshow 2000), we used generalized linear mixed-models (GLMM) with a random-intercept for individual to allow for interpretation of selection among different populations and species (Hebblewhite et al. 2008; Bolker et al. 2009), thus accounting for temporal and spatial autocorrelation among individuals and groups (Breslow and Clayton 1993) and correcting for unbalanced number of locations among individuals (Bennington and Thayne 1994). Furthermore, data were pooled by month for each animal (i.e., Animal1_June2010, Animal2_June2010, Animal1_July2010, etc.) to provide a population estimate across the summer months while taking into account changing availability in our dynamic measure of vegetation productivity, NDVI.

We estimated RSFs at the third order scale (Johnson 1980) on APR, GNP, and cattle ranches. On APR and cattle pastures, we randomly sampled monthly availability ($n=1\,000$) across individual months within a given pasture for bison and cattle. In GNP we randomly sampled monthly availability ($n=1\,000$) within a 95% fixed kernel monthly home range (third order) using Geospatial Modeling Environment 6.0 (Beyer 2012). In GNP, we also estimated RSFs at a constrained second order scale (i.e., pasture unit) by randomly sampling monthly availability ($n=2\,000$) across the entire park to understand whether resource selection differed across spatial scales in GNP. We define this as constrained second order resource selection because the area is used throughout the year; however, we cannot explicitly state whether this area would encompass the bison's annual population range if no peripheral fence existed. A GLMM was estimated using the lme4 package (Bates et al. 2011) for R 2.15.1 and included our covariates (described above). For categorical covariates, we selected riparian communities as the reference category for vegetation due to previous relationships between riparian communities and bison and cattle reported in the literature. East-facing slopes were selected as a reference category in relation to other cardinal directions because of perceived heat exposure. We assumed that north-facing slopes were cooler, and west- and south-facing slopes were warmer than east-facing slopes, thus influencing the selection of aspect. All variables were screened for collinearity by calculating the Pearson's correlation between variables and using $r > 0.6$ as the threshold for removing a covariate (Hosmer and Lemeshow 2000). Because analysis coefficients are relative to all other model variables,

Table 2. Chi-square comparison of bison and cattle behavior across and within species. Behavioral activities were observed from 23 May to 31 August (2010, 2011) of bison on American Prairie Reserve (APR) and Grasslands National Park (GNP) and cattle on Barnard Ranch (BR) and Weiderrick Ranch (WR). χ^2 results represent the comparison of a specified behavior against four additional behaviors. Data were pooled across years for each site and pooled across years and sites for species.

	Species comparison			Bison location comparison			Cattle location comparison		
Behavior	x^2	df	P	x^2	df	P	x^2	df	P
Grazing	1054.02	1	< 0.01	5.17	1	0.02	11.97	1	< 0.01
Standing	165.81	1	< 0.01	23.55	1	< 0.01	17.47	1	< 0.01
Bedded	1068.21	1	< 0.01	0.06	1	0.80	30.87	1	< 0.01
Moving	245.76	1	< 0.01	87.68	1	< 0.01	50.46	1	< 0.01
Other	4.39	1	0.04	0.23	1	0.63	60.58	1	< 0.01

no model selection technique was used, thus allowing a more direct comparison of covariates across location and species.

RESULTS

Behavior

Cattle and bison species differed ($P < 0.01$) in all behaviors (grazing, bedded, moving, standing, other [Table 2]) with cattle spending proportionately more time grazing and less time moving than bison (Table 3). However, the importance of landscape attributes was highlighted as both species demonstrated behavior differences across study sites. Bison behaviors differed ($P = 0.02$) between APR and GNP for grazing, standing, and moving, but not for bedded or other behaviors (Table 2). Similarly, cattle behaviors differed ($P < 0.01$) between BR and WR for all behaviors (Table 2).

Cattle spent more time at water than bison ($F_1 = 75.07$, $P < 0.01$). Cattle on BR (3.47 ± 0.27 min) and WR (4.44 ± 0.77 min) did not differ in time spent at water ($F_1 = 2.29$, $P < 0.13$). However, bison on APR (2.17 ± 0.11 min) and GNP (1.52 ± 0.09 min) differed in time spent at water ($F_1 = 19.68$, $P < 0.01$). Furthermore, the influence of temperature was dependent on the sampling location ($F_5 = 9.12$, $P < 0.01$ [Fig. 2]).

Movement

Cattle did not differ in MR across pasture units ($\beta = -0.17 \pm 0.27$ SE, $P = 0.206$), thus MR of both cattle sites were combined. In comparison, bison moved faster than cattle ($\beta = 0.62 \pm 0.08$ SE, $P < 0.01$). However, bison MR differed across sites ($\beta = -0.28 \pm 0.10$ SE, $P < 0.01$), with bison on GNP moving at a 25% faster rate than bison on APR. Thus, we compared combined cattle MR to location-specific bison MR. Following our prediction, bison exhibited faster MR on APR ($\beta = 0.41 \pm 0.11$ SE, $P < 0.01$) and GNP ($\beta = 0.69 \pm 0.0822$ SE, $P < 0.01$) than cattle. After β transformation, this equates to bison on APR and GNP moving at a 51% and 99% faster rate than cattle.

Table 3. Proportion of time of behavioral activities observed from 1 June to 31 August (2010, 2011) of bison on American Prairie Reserve (APR) and Grasslands National Park (GNP) and cattle on Barnard Ranch (BR) and Weiderrick Ranch (WR). Data were pooled across years.

	Bison		Cattle	
Behavior	APR	GNP	BR	WR
Grazing	0.26	0.28	0.45	0.49
Standing	0.15	0.18	0.24	0.20
Bedded	0.46	0.46	0.23	0.29
Moving	0.11	0.08	0.05	0.02
Other	0.02	0.02	0.02	0.00

Variance in FPT was maximized at 5 162 ± 13 (patch area = 8 368 ha) and 6 100 ± 173 (patch area = 11 690 ha) m radii for bison in APR and GNP (Fig. 3), respectively, whereas variances of cattle on BR and WR were maximized at 2 785 ± 103 (area = 2 435 ha) and 3 040 ± 254 (area = 2 901 ha) m radii, respectively (Fig. 3). Bison in GNP also showed increased variance in FPT at 9 904 ± 374 m radii; however, no large-scale response was found on APR (Fig. 3). Cattle on BR demonstrated a hierarchical response at a within-pasture-unit scale of 395 ± 53 m radii or 49 ha (Fig. 3). Cattle on WR also appeared to respond to resources at a fine scale (1 400 ± 450 m or 615 ha) in 2011; however, no response was observed in 2010.

Resource Selection

Cattle. Selection or avoidance of pasture attributes (except aspect) was similar across years and sites for cattle on BR and WR (Table 4). Cattle at both sites demonstrated strong selection for water resources and low elevations. Cattle on BR selected areas closer to roads; however, no comparison of road use by cattle on WR was possible because no major roads existed in the pasture unit. Cattle (across sites) avoided steep slopes and all vegetation types in relation to riparian communities. Cattle also demonstrated a linear response to NDVI (Fig. 4).

Bison. Resource selection by bison on APR (Table 4) was similar across years except for distance to fencing and sagebrush-steppe communities. Bison selected for sagebrush-steppe communities (relative to riparian communities) and areas farther from fencing in 2010 and avoided sagebrush-steppe communities (relative to riparian communities) and areas closer to fencing in 2011. There was no clear trend related to aspect across years. Bison selected for water sources and areas of higher elevation while avoiding roads and steeper slopes. Resource selection by bison in GNP (Table 4) within the constrained

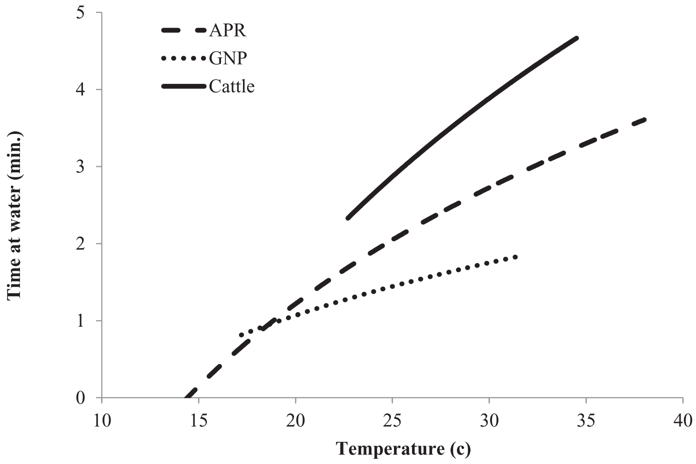

Figure 2. Influence of temperature on water use by bison on American Prairie Reserve (APR) and Grasslands National Park (GNP) and cattle on Barnard Ranch (BR) and Weiderrick Ranch (WR). Cattle did not statistically differ in time spent at water across two study locations, thus data were combined.

second order (pasture unit) and third order (summer range) demonstrated similarities to APR bison for pasture attributes across time and space, particularly in selection of water sources and areas of higher elevation. Bison in GNP avoided steep slopes and most vegetation communities relative to riparian communities, including sagebrush-steppe, upland grassland, and disturbed communities across time and space.

DISCUSSION

Interest in bison and prairie conservation has been renewed with conservationists questioning the impacts of, and differences between, domestic and native grazers at a landscape scale. Bison and cattle share a common ancestry; however, evolutionary changes that have occurred over the past 600 000 yr (MacHugh et al. 1997) lead to questions of whether the two species are, or can, serve as ecological synonyms of one another. Furthermore, complications arise when addressing these questions when bison and cattle are placed under different management strategies (Fuhlendorf et al. 2010).

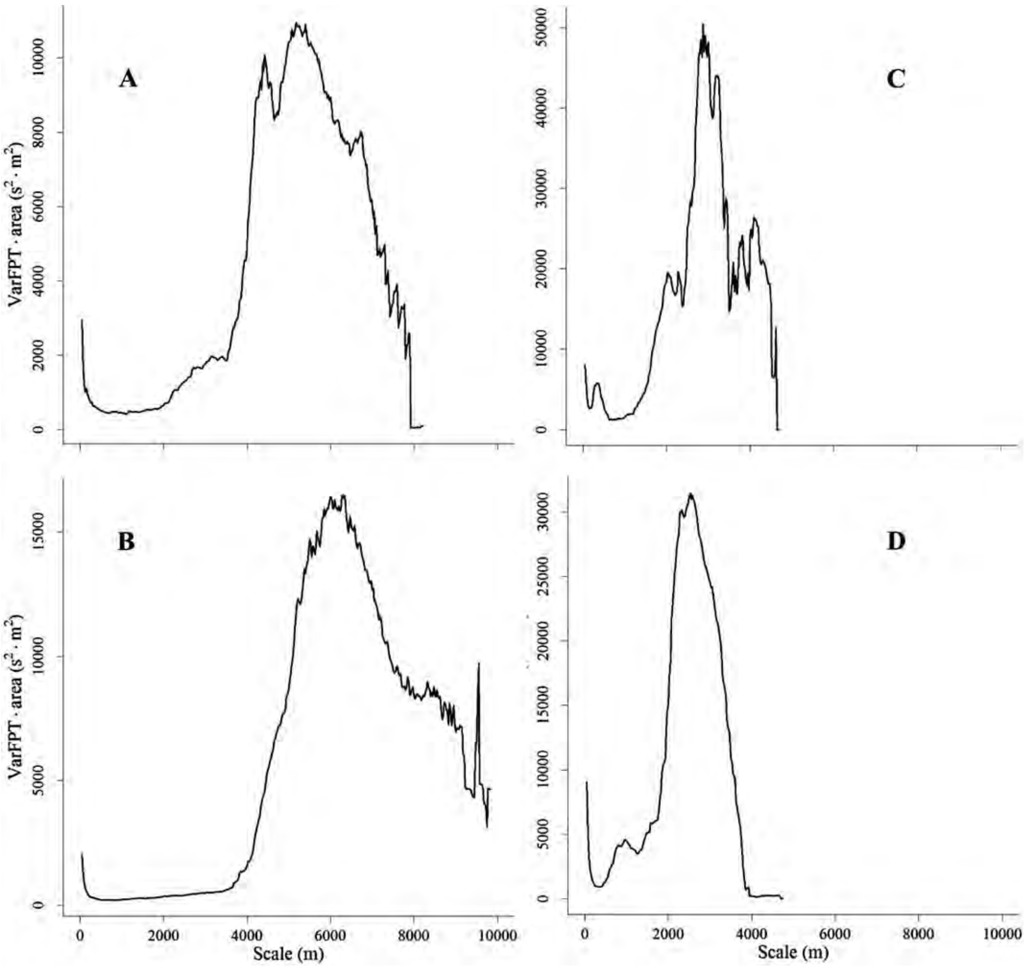

Figure 3. Examples of First Passage Time (FPT) analysis for one female bison during summer 2010 on American Prairie Reserve (**A**) and in Grasslands National Park (**B**) and for one domestic female during summer 2010 on Barnards Ranch (**C**) and on Weiderrick's Ranch (**D**). Peaks in variance of FPT (plotted up to 10 000 m) identify the spatial scale at which consumers perceive their resources. *X* axis is a measure of a circle's radius.

Table 4. Coefficient estimates from Resource Selection Functions of summer 2010 and 2011 bison use on American Prairie Reserve (APR) and Grasslands National Park (GNP). Analysis was calculated within summer range (summer) and within annual range (annual) in GNP. Coefficient values were calculated for cattle on Barnard (BR) and Weiderrick (WR) ranches. Dashes identify nonsignificant values. Variables unavailable for calculation are identified by NA. East aspect and riparian vegetation were used as reference categories. Significance at > 0.05.

Behavior

Historical accounts report that bison would graze for multiple days over distances of 80–160 km before watering, at which time they would drink heavily (Hornaday 1887a; Dary 1989). In agreement, van Vuren (1979) reported bison watering events to last 21.3 minutes in a desert landscape. However, we observed shorter watering times than those presented above. This may be due to high precipitation levels during the study, which permitted numerous short bouts of water acquisition from ephemeral water sources. The differences in water use between species, however, does provide insight into the water requirements of bison, including physiological capabilities that would permit water source removals that may lead to increased vegetation heterogeneity at a landscape scale.

Bison spent less time grazing than cattle in our study, in agreement with Plumb and Dodd (1993). However, their study reported the amount of grazing time during summer (June–October) increased from 47% to 67% for bison and from 51% to 71% for cattle. The large difference in time spent grazing by bison reported in the literature and in this study (APR=26%, GNP=28%) may be a result of different observation techniques in which group behavior (previous study) or individual behavior (this study) was recorded, thus resulting in an inability to directly compare results. However, our observations of increased grazing and decreased movements by cattle, when combined with livestock stocking levels twice that of historic bison, is compatible with the hypothesis that current range practices are resulting in homogenous grazing at a landscape scale, and thus contributing to the continued decline of prairie obligate species (Knopf 1996; Fuhlendorf et al. 2006).

Movement

Bison are effectively extinct at what are thought to be ecologically relevant scales (Freese et al. 2007). However, a definition of this spatial scale for bison has, until recently, been subjective. Lott (2002) approximated an ecological functional scale for a bison herd to be as large as 1 300 000 ha and, Sanderson et al. (2008) stated that landscapes > 200 000 ha are exceptional contributors to the ecological recovery of bison, yet little quantitative work has demonstrated the true scale that bison require.

We identified hierarchical foraging scales for cattle, indicating use of the entire pasture with movements also organized at subpasture unit scales. These smaller scales suggest that cattle perceive and move in response to landscape patches corresponding with contemporary range management guidelines that assume distances of 1.6–3.2 km from water to be of moderate forage availability and further distances considered ungrazeable by cattle (Holecheck et al. 2006). Under these guidelines, the total area surrounding a singular water resource encompasses < 813.25 ha of forage availability for cattle, lending credibility to our observations of 49 ha (BR) and 615 ha (WR) foraging patches. In comparison, bison indicated no peaks in FPT at subpasture scales. The lack of small-scale patch use by bison within APR suggests that a single bison foraging patch encompasses an area of at least the APR pasture unit (3 555 ha). These results

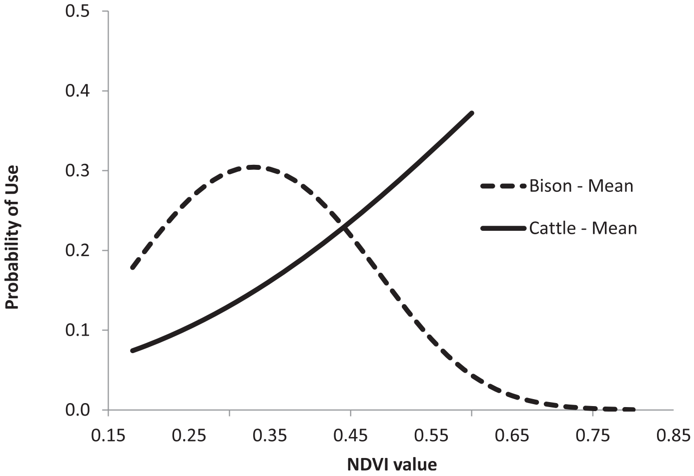

Figure 4. Averaged probability of use for intermediate green vegetation (NDVI values) for bison (at summer and annual scale) and cattle for all values (i.e., significant and nonsignificant). Selection was calculated from maximum and minimum NDVI values only and was fitted to a quadratic relationship for both species to identify whether selection was occurring for intermediate forage biomass.

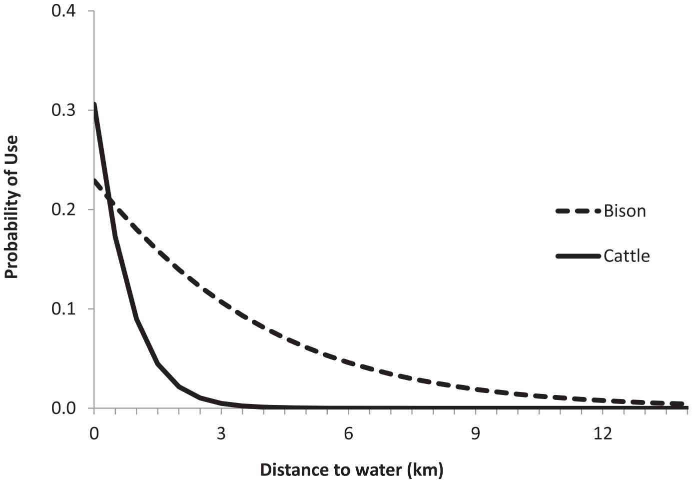

Figure 5. Probability of use for bison and cattle in relation to distance to water. Calculated using averaged values from RSF across years and locations for bison and cattle on GNP and APR.

are confirmed when we identified a bison summer foraging patch to be $\sim$11 683.94 ha in GNP where a larger pasture unit permits increased movement and landscape use. Furthermore, the largest scale identified in GNP may approximate a spatial scale used when historical bison populations are permitted to move freely across the landscape. Thus, we provide the first quantitative evidence within the Great Plains region that bison populations use larger spatial scales than cattle and may prefer larger landscapes than currently provided by managers and, as a result, would likely make different ecological contributions at such scales. In addition, FPT identifies a single resource patch, implying that multiple large patches are necessary, particularly when considering long temporal scales that bison may have used historically (i.e., overgrazing leading to landscape movements the following month, season, or year [Seton 1929]).

Previous studies using FPT to identify scales of movement by large herbivores have not examined the impact of a defined boundary (i.e., fencing) on detected scales (Frair et al. 2005; Williams et al. 2012). The fact that our FPT analyses identified scales of movement larger than the area of the fenced pasture is a result of using increasing radii around each GPS observation (i.e., the circles extend beyond the fence). We have interpreted these results as indicating that the individuals' movements are organized at a scale consistent with at least the entire pasture unit.

Resource Selection

Cattle located on the BR and WR demonstrated strong selection for riparian areas, lowlands, and water resources as predicted by other studies (van Vuren 1983; Allred et al. 2011). For bison, our results were similar to previous research in that bison selected for higher elevations (van Vuren 1979; Phillips 2000); however, we report avoidance of most vegetation communities by bison populations on APR and GNP in relation to riparian areas, a finding contrary to previous literature. These riparian areas were generally located within steep drainage areas where water availability may have existed and may have resulted in short, opportunistic watering events when bison were nearby, thus explaining the selection of these areas.

We are the first to observe selection of water resources by bison across location and spatial scale, a finding contrary to other work throughout the literature (van Vuren 1979; Phillips 2000; Babin 2009; Allred et al. 2011). As expected, we report strong selection for water by cattle with no expected use beyond 3 km from water, or ≤ 707 grazeable ha $\cdot$ water source (GH; Fig. 5). Bison selected for water, however they still used areas more than 10 km from water sources, a finding similar to McHugh (1958; Fig. 5). This is in contrast to other work and our expectations based on the abundance of ephemeral water but may simply be due to an inability to avoid water as a result of the significant precipitation during the study. Last, we confirmed the historic importance of summer temperatures on water requirements (Hornaday 1887a).

In terms of grazing, NDVI has been demonstrated as a viable metric for quantifying quality (i.e., standing nitrogen) and quantity (i.e., total biomass) in the study region (Thoma et al. 2002), thus allowing for the identification of tradeoffs between forage quality and quantity (Fryxell 1991). We report different selection relationships for forage quality/quantity by bison and cattle (Fig. 4). A quadratic relationship was fitted to each species to maintain consistency within the study; however, it is evident that cattle may be maximizing intake rate by selecting areas of higher forage biomass if maximum net energy intake occurs at intermediate biomass (where daily energy intake and forage biomass intersect [Hebblewhite et al. 2008; Fryxell 1991]). Previous work has varied across studies with cattle selecting for maximum intake (Distel et al. 1995), previously grazed areas (Silvia Cid and Brizuela 1998), higher forage quality (Bailey 1995), or areas of intersecting forage quantity and quality (Senft et al. 1985). Similar to other studies (Coppock et al. 1983; Coppedge and Shaw 1998; Bergman et al. 2001), bison selected for intermediate biomass (Fig. 4) except at the third order scale in 2011 on APR and GNP. We hypothesize these differences in 2011 are due to abundant rainfall throughout the year that may have resulted in areas of high biomass with abnormally high nutrient quality, thus relaxing the trade-off between forage quality and quantity.

IMPLICATIONS

If increased biological diversity facilitated by vegetation heterogeneity is an objective (Fuhlendorf et al. 2006) and domestic livestock are used as the dominant grazer, then the cumulative result of grazing alterations across many pasture units may reduce the impact of increased grazing periods and localized use areas by livestock, thus increasing biological diversity at a landscape scale (Fuhlendorf and Engle 2001). Potential pasture unit alterations may include changes to timing, duration, and intensity of grazing or through the use of transportable water and/or mineral sources (Ganskopp 2001; Porath et al. 2002; Bailey 2004).

If increased vegetation heterogeneity through bison grazing is an objective, then we have demonstrated that much larger pasture units may be required to facilitate bison movement, behavior, and resource use that more closely approximates historical bison populations. Although we have not quantified the pasture unit size that would permit approximations of historical use, we have provided quantitative support for the contribution of nonconstricted bison populations or populations within large pasture units to landscape vegetation heterogeneity in the Great Plains region. Due to the limited area of availability for bison in this study, we encourage similar movement analyses to be adapted to bison populations with less anthropogenic, biological, or social constrictions, thus providing additional insight into the scale of bison use across time and space. Within bison conservation areas, we have identified resources of value including variable vegetation communities that occur across upland and lowland areas. Also, we recommend testing the minimum spatial requirements of water by bison through water source reductions, thus encouraging long distance movements across the landscape that facilitate grazing heterogeneity similar to historic use (Hornaday 1887b).

ACKNOWLEDGMENTS

We thank the Weiderrick and Barnard ranches for providing access to their property and technicians K. Plourde, K. Gunderson, A. Derey-Wilson, and T. King. We thank B. Christensen and S. Gerrity (APR) and S. Forrest, C. Freese and M. Kauffman (WWF) for advice, review, and logistical support of this project. We appreciate the comments of two anonymous reviewers.

ABSTRACT / Prairie dogs (*Cynomys* spp.) have been labeled as keystone species because of their influence on biological diversity and ecosystem function. However, the validity of several assumptions used to support keystone status is questionable. We review the strength of the evidence and the magnitude of the prairie dog's effects on ecosystem structure and function. We use this review to reevaluate the keystone role for prairie dogs. Our goal is to encourage sound management of the prairie dog ecosystem by improving the ecological foundation of their keystone status.

Our review confirms that prairie dogs affect a number of ecosystem-level functions but that their influence on prairie vertebrates may be less than previously suggested. Species richness and abundance patterns were variable among plants, mammals, and birds and were not consistently higher on prairie dog colonies compared to uncolonized areas. In addition, only nine of the 208 species listed in the literature as observed on or near prairie dogs colonies had quantitative evidence of dependence on prairie dogs. Abundance data indicated opportunistic use of colonies for an additional 20 species. A total of 117 species may have some relationship with prairie dogs, but we lacked sufficient data to evaluate the strength of this relationship. The remaining 62 species may be accidental or alien to the system.

Despite our conclusion that some prairie dog functions may be smaller than previously assumed, collectively these functions are quite large compared to other herbivores in the system. We suggest that prairie dogs also provide some unique functions not duplicated by any other species and that continued decline of prairie dogs may lead to a substantial erosion of biological diversity and landscape heterogeneity across prairie and shrub-steppe landscapes. Thus, we concur that keystone status for prairie dogs is appropriate and may aid conservation efforts that help protect species dependent on prairie dogs and support other important ecosystem functions.

The much maligned prairie dog has been the target of widespread eradication campaigns over the past century, largely as a consequence of their reputation as range and agricultural pests (Clark 1989). Sylvatic plague and habitat loss have also contributed to the estimated 98% population decline in prairie dog numbers (Marsh 1984, Anderson and others 1986, Miller and others 1990, Cully 1993). Particularly severe reductions of the Utah prairie dog (*Cynomys parvidens*) have prompted its listing as a federally threatened species.

Where prairie dogs still persist, they conspicuously alter prairie landscapes and provide foraging, shelter, and nesting habitat for a diverse array of species. Prairie dogs serve as prey for a number of predators including black-footed ferrets and prairie rattlesnakes (see Appendix 1 for scientific names). Their burrows provide nest sites and shelter for vertebrates such as tiger salamanders and burrowing owls, as well as for invertebrates. Prairie dogs alter plant species composition and vegetation structure (Whicker and Detling 1988), creating open habitats. They also can affect ecosystem processes such as disturbance and nutrient cycling rates (Whicker and Detling 1988).

Prairie dogs have been labeled a keystone species based on the assumption that they have a pronounced effect on biological diversity in prairie systems (Reading and others 1989, Miller and others 1994, Benedict and others 1996, Roemer and Forrest 1996, Weltzin and others 1997a, Wuerthner 1997). It has been argued that if we save prairie dogs, we save a key component of the prairie ecosystem that includes declining grassland species considered dependent upon prairie dog colonies for survival (Miller and others 1990, 1994). Thus, prairie dogs have been targeted as a conservation

priority. Indeed, the black-tailed prairie dog (*C. ludovicianus*) was recently petitioned to receive candidate species status under the Endangered Species Act, based in part on its role in supporting numerous dependent species (Biodiversity Legal Foundation and Sharps 1994). This petition was denied, in part, because the petitioners' conclusions about the purported keystone role of prairie dogs in the prairie system were deemed equivocal (Gill 1995).

Prairie dogs clearly have an important role in grassland systems. It is our premise, however, that the magnitude of the prairie dog's role has been overstated in the literature. Here we review the evidence supporting the following assumptions that have been cited as evidence of their keystone role: (1) prairie dogs regulate ecosystems (Hansen and Gold 1977, O'Meilia and others 1982, Agnew and others 1986, Miller and others 1990); (2) passerine, small mammal, and predator abundance is higher at colonies (O'Meilia and others 1982, Clark and others 1982, Agnew and others 1986, Krueger 1986, Sharps and Uresk 1990, Reading and others 1989, Miller and others 1990, 1994); (3) species richness and diversity is higher at colonies (Hansen and Gold 1977, O'Meilia and others 1982, Agnew and other 1986, Clark and others 1982, Reading and others 1989, Sharps and Uresk 1990, Miller and others 1990, 1994); and (4) over 200 vertebrate species are associated with prairie dog colonies (Campbell and Clark 1981, Clark and others 1982, Reading and others 1989, Sharps and Uresk 1990, Biodiversity Legal Foundation and Sharps 1994, Miller and others 1990, 1994). We reviewed over 200 references on prairie dogs and associated taxa dating back as early as 1902. We focus on black-tailed prairie dogs because they are the most extensively studied and the most widely distributed of the prairie dog species, but also include evidence for Mexican prairie dog (*C. mexicanus*), white-tailed prairie dog (*C. leucurus*), Utah prairie dog, and Gunnison's prairie dog (*C. gunnisoni*).

Based on the strength of existing evidence, we then reevaluate whether prairie dogs function as a keystone species. We use Paine's (1969) original definition of keystone species, which reflects species whose activities greatly influence the composition, integrity, and functioning of communities. We also use a more recent definition proposed by Power and others (1996), who define a keystone species as one whose overall impact on a community is large, as well as disproportionately large relative to its abundance. We conclude that although some aspects of their role have been overstated in the literature, the available evidence clearly indicates that prairie dogs function as a keystone species. We also suggest that only well-documented ecological functions of prairie dogs should be the basis for management decisions.

Review of the Prairie Dog's Role

Ecosystem Regulation

The disturbance caused by grazing and burrowing activities of prairie dogs affects a number of ecosystem-level processes (Whicker and Detling 1988). Prairie dog grazing affects vegetation structure by decreasing vegetation height and cover and altering plant species composition (Coppock and others 1983a, Brizuela and others 1986, Cid and others 1989, Cincotta and others 1989, Weltzin and others 1997a,b). Prairie dog burrowing and grazing can also affect the rates of nitrogen cycling and lead to increased nitrogen uptake by plants (Holland and Detling 1990), which may account for the preferential grazing of prairie dog colonies by pronghorn, elk and bison (Coppock and others 1983b, Krueger 1986, Wydeven and Dahlgren 1985). Below ground, prairie dogs increase soil mixing and affect rates of energy and material flows (Ingham and Detling 1984). Across the landscape, variation in colony density and duration of occupancy can lead to a shifting mosaic of patches that differ in vegetation structure, composition, and quality (e.g., nutrient availability) within and among patches (Bonham and Lerwick 1976, Archer and others 1987). Cumulatively, prairie dog activities influence patch dynamics and contribute to overall landscape heterogeneity.

Superimposed over the disturbance caused by prairie dogs are the impacts of fire and climatic variability. These processes generally operate at spatial scales much greater than the scale of individual prairie dog colonies, although human activities have decreased the scale of both fire and prairie dog disturbance regimes. The patch-level disturbance created by prairie dogs interacts with these large-scale disturbances, altering their effects on landscape structure and dynamics (Coppock and Detling 1986, Weltzin and others 1997a). For example, prairie dog colonies may serve as fire breaks and may also magnify the effects of cyclical and seasonal drought. Higher than average rainfall may either enhance or diminish the effects of prairie dog disturbance. Historically, bison were also an important agent of disturbance across the Great Plains and may have influenced the dispersal and distribution of prairie dogs and may have selectively grazed prairie dog colonies (Coppock and others 1983b, Krueger 1986, Wydeven and Dahlgren 1985).

Collectively, these direct and indirect impacts of prairie dog grazing and burrowing have a pronounced effect on ecosystem processes and patterns, even though prairie dog numbers are only a fraction of historic levels. Considering that the historic range of prairie dogs may well have covered over 40 million ha (Anderson and others 1986), their impact on landscape structure and dynamics must have been dramatic.

Abundance Patterns

It is frequently cited that the overall abundance of birds, small mammals, and terrestrial predators is higher on colonies (O'Meilia and others 1981, Clark and others 1982, Agnew and others 1986, Reading and others 1989, Miller and others 1990, 1994, Sharps and Uresk 1990). However, several details have been omitted that bear on the interpretation of these patterns. The higher abundance (total individuals) of small mammals and passerines on colonies relative to adjacent areas (O'Meilia and others 1982, Agnew and others 1986, Mellink and Madrigal 1993, Barko 1996) can be accounted for solely by the abundance patterns of deer mice, grasshopper mice, and horned larks. Higher terrestrial predator abundance is based on the statement that "dog towns had 5.7 times the frequency of predators (coyotes and badgers) as off-town areas" (Krueger 1986); however, the validity and generality of this pattern cannot be evaluated because no information on methods and analysis were provided in this paper.

Species Richness Patterns

Keystone species commonly affect community structure by increasing species richness (Mills and others 1993). Although it is widely stated that prairie dogs can increase species richness (Hansen and Gold 1977, Clark and others 1982, O'Meilia and others 1982, Reading and others 1989, Miller and others 1990, 1994), prairie dogs do not appear to consistently increase species richness and may sometimes decrease richness at the scale of individual colonies. Agnew and others (1986) found that out of a total of 39 bird species, 36 species occurred on colonies compared to 29 species off colonies, a pattern frequently used to assert the keystone role of prairie dogs (Reading and others 1989, Miller and others 1990, 1994). Although the entire list of 36 species observed on colonies was not provided, their results indicate that at least seven of these species were from a species pool that included exotics (rock dove, European starling, house sparrow) or waterbirds (mallard, northern pintail, blue-winged teal, sora, yellow-headed blackbird). It is unlikely these species evolved a strong relationship with prairie dogs. In a similar study, 30 species were found on colonies compared to 27 species in adjacent uncolonized areas (Barko 1996). Thus, the available evidence indicates that there may be only a minimal contribution to colony-scale biological diversity accounted for by an increase in avian species richness on colonies.

For small mammals, species richness may actually be lower on colonies compared to nearby uncolonized areas (O'Meilia and others 1982, Agnew and others 1986, Mellink and Madrigal 1993). In addition, several species of rodents observed in uncolonized areas are completely absent from colonies (O'Meilia and others 1982, Agnew and others 1986, Mellink and Madrigal 1993). This pattern often has been overlooked in summaries of the prairie dog's role.

Plant species richness is probably related to the degree of prairie dog disturbance. Intermediate disturbance levels have the greatest floral species richness, although this pattern varies somewhat among forbs, grasses, and shrubs (Whicker and Detling 1988). Plant species richness can also vary within colonies as a function of colony age (Whicker and Detling 1988). In addition, species richness patterns may vary across seasons, vegetation types (e.g., shortgrass prairie vs shrub-steppe), and prairie dog species (Weltzin and others 1997b).

This confusing array of richness patterns indicates that using these patterns to characterize the role of prairie dogs is problematic. Species richness at the scale of colonies provides little information about how prairie dogs influence the integrity of the community. This is better addressed by comparing species composition, which can differ among areas with and without prairie dogs. Many plant and animal species reach their highest densities on colonies. For example, the reduction of little bluestem (*Andropogon scoparius*) on black-tailed colonies may allow annual forbs, such as prairie dogweed (*Dyssodia papposa*) to increase in abundance relative to undisturbed prairie, where they are quite rare (Coppock and others 1983a). In mesquite grasslands, historic populations of black-tailed prairie dogs, in conjunction with other herbivores associated with colonies, may have prevented woody species such as mesquite (*Prosopis* spp.) from attaining dominance (Weltzin and others 1997a). Thus, changes in species composition resulting from prairie dogs can increase species richness, but at scales much larger than previously studied.

Dependence of Vertebrates on Prairie Dog Colonies

Criteria for establishing dependence. Another way to evaluate the influence of prairie dogs on the integrity of the system is to quantify the degree to which species depend on prairie dogs. We defined dependent species as those species whose fitness is increased by the

Table 1. Strength of dependence/association of 208 vertebrate species found in proximity to prairie dog towns

Strength of association	Definition	If prairie dogs go extinct	Possible examples
Dependent species			
Obligate	Almost totally dependent upon prairie dogs for survival	Species goes extinct	Black-footed ferret
Facultative			
Strong	Use one or more features of prairie dog towns that have limited availability off towns	Decrease in local and regional abundance	Burrowing owl, mountain plover
Weak	Use features of prairie dog towns that are also abundant off towns, or use of towns varies in space or time	Abundance may decrease locally if alternative habitats limiting	Ferruginous hawk, horned lark
Associated species			
Opportunistic	Species more generally associated with prairie grasslands; occur on prairie dog towns, but tend to be more abundant off towns	Little or no change in abundance; may increase if undisturbed habitat preferred	Western diamondback rattlesnake, western meadowlark, pronghorn
Accidental	Do not use features of towns, but are seen on, or near, towns due to habitat features that occur in proximity to towns	No change likely	Yellow warbler, white pelican, ladder-backed woodpecker
Alien	Exotic or domestic animals	No change likely	Domestic cattle, house sparrow, Norway rat

presence of prairie dogs, which included both obligate (require prairie dogs for survival) and facultative species (use features of prairie dog colonies that have limited availability elsewhere; Table 1). We compiled a list of 208 vertebrate species that have been cited as associated with prairie dogs (Appendix 1; references in Table 2). Prairie dog associates have been minimally defined as those species seen on, near, or flying over prairie dog colonies and does not reflect use of prairie dog colonies. Consequently, this list includes species that range in association from obligate species to species associated with habitat features (e.g., wetlands, reservoirs, trees) located on or near colonies that are not a consequence of prairie dog activities (Table 1). We developed four criteria to determine which of the 208 species listed as prairie dog associates are truly dependent upon prairie dogs:

1. *Abundance of species is higher on prairie dog colonies than comparable areas without prairie dogs.* In general, a greater disparity in abundance indicates a greater degree of dependence. However, because this criterion is based on correlational patterns, it provides only weak evidence of dependence.

2. *Species use features of prairie dog towns, which are a direct consequence of prairie dog activities or presence, at greater frequencies than similar features off colonies.* This criterion helps to quantify the degree of specialization on features of prairie dog colonies. For instance, burrowing owls may use prairie dog burrows at a greater frequency than the burrows of other species.

3. *Survivorship or reproductive success is lower off prairie dog colonies than on colonies.* Thus, colonies may serve as sources of recruitment, whereas alternative habitats may constitute ecological sinks that require continued immigration to maintain populations. For example, although mountain plovers and horned larks sometimes nest on agricultural land, agricultural practices may reduce nest success (Hurley and Franks 1976, Knopf and Rupert 1998).

4. *Populations of dependent species decline if prairie dog populations decline.* Declines in strongly dependent species should occur both locally and regionally if prairie dogs are extirpated. Species only marginally dependent on colonies might decline locally, but not regionally, if availability of alternative habitats is sufficient to support populations elsewhere across their range. For example, in several areas in Colorado and New Mexico, wintering and migrating ferruginous hawk numbers declined locally following a crash in prairie dog populations as a result of a sylvatic plague (*Yersinisia pestis*) epizootic (Jones 1989, Cully 1991). Evidence of meeting this criterion, particularly in combination with decreased fitness off colonies, is the most compelling support for dependence.

Documenting dependence on prairie dogs is rather difficult. Because dependence can vary in space and time, scale of analysis is crucial. For example, horned larks may be more abundant on colonies compared to nearby undisturbed areas (Agnew and others 1986, Barko 1996), but may reach numbers comparable to

that found on colonies on otherwise disturbed prairie habitat or outside the prairie dogs' range (Hurley and Franks 1976). Taken individually, each criterion cannot sufficiently rule out alternative explanations for correlational patterns consistent with dependence. For example, secretive species may appear more abundant on colonies than in adjacent taller vegetation merely because of detection differences. In addition, failure to meet a specific criterion could result from lack of data, because not all criteria are required for dependence, or because a species is truly not dependent on prairie dogs. Thus, nondependent species may sometimes appear to meet a single criterion or dependent species may not satisfy every criteria. Convincing evidence of dependence on prairie dogs will generally require meeting more than one criterion but not necessarily all four.

Results of dependence analysis. We found that few of these criteria were met by most presumed prairie dog associates. Only nine vertebrate species had data documenting at least one of the four criteria (Table 3). Furthermore, data addressing fitness (criterion 3) was available for only two species. Other vertebrate species (e.g., badger, tiger salamander, prairie rattlesnake) are often assumed to be dependent on prairie dogs, but there are currently no published data to support this. Further work is clearly needed to confirm, or rule out, dependence for many of these candidate dependent species and to determine if other species meet any of the four dependence criteria.

Species ranged in their degree of association from obligate to opportunistic use of colonies (Table 1). Only one species, the black-footed ferret, is truly an obligate. This species is near extinction primarily due to a range-wide decimation of the prairie dog ecosystem, in conjunction with secondary poisonings and susceptibility to distemper and plague (Clark 1989). Mountain plovers and burrowing owls may be strongly facultative species because they apparently have suffered population declines within the prairie dog's range following declines in prairie dogs. These three species had the strongest evidence for dependence.

The remaining six candidate dependent species had weaker evidence of dependence and each met only one

of the four criteria (Table 3). These species would probably decline locally following a decline in prairie dogs if alternative prey or habitat were unavailable (i.e., weakly facultative; Table 1). Examples include ferruginous hawks, golden eagles, and swift foxes, which are generalist predators that likely feed on prairie dogs in an opportunistic manner, but may specialize locally on prairie dogs when alternative prey sources are scarce. Evidence of dependence by ferruginous hawks and golden eagles is indicated by local declines during migration and on wintering grounds in New Mexico and Colorado following prairie dog population declines (Jones 1989, Cully 1991). In addition, wintering ferruginous hawks in Colorado typically have higher abundances on prairie dog colonies than areas without prairie dogs (Kotliar, unpublished data). A decline in swift foxes in South Dakota was also observed following declines in prairie dogs (Sharps 1989). South Dakota is the only area where data indicate that prairie dogs comprise a sizable proportion of the swift fox diet (Hillman and Sharps 1978, Uresk and Sharps 1986), which is otherwise usually dominated by nocturnal rodents (Kilgore 1969). The other three weakly facultative species (horned lark, deer mouse, and grasshopper mouse) are generalists that use open areas created by prairie dog activities. Horned lark abundance was one to two orders of magnitude higher on prairie dog colonies compared with uncolonized grasslands (Agnew and others 1986). Deer mice and grasshopper mice, although relatively abundant off colonies, were observed at densities three to four times higher on prairie dog colonies compared to uncolonized grassland (O'Meilia and others 1982, Agnew and others 1986). The degree to which any of these species would actually decline or simply move elsewhere if prairie dogs decline, however, is unclear and depends on whether prey, burrows, or open habitat is limiting. However, the limited data suggest that prairie dogs may influence the distribution patterns of these six species across the landscape.

What about the remaining 199 associated species? Abundance data for criterion 1 were only available for 20 species: five species reached slightly higher abundance levels on colonies, five species had similar abundance levels on and off colonies or had mixed patterns, and ten species had higher abundance levels off colonies (Appendix 1). This indicates that these 20 species at least occasionally occur on colonies, but probably do not prefer colonies, and may even prefer undisturbed grasslands (e.g., grasshopper sparrow).

An additional 117 species lacked abundance data on and off colonies, but their life history information indicated they could potentially use colony attributes. This included species that are often presumed to be prairie dog dependents (e.g., tiger salamander, prairie rattlesnake, badger), but which lack data to document dependence. It also included species such as western harvest mice that may actually prefer undisturbed grasslands. Fifteen species use ephemeral pools that sometimes develop on colonies. Prairie dogs may not be responsible for the rare occurrence of these shallow ponds, but their activities keep them relatively free of vegetation, a condition that may be preferred by amphibians and shorebirds that use these pools.

Of the remaining 62 species, 10 are domestic and exotic species (Table 1). Most of the remaining 52 species are waterbirds, more commonly associated with deep water (e.g., waterfowl, pelicans), that may have been observed flying over, or near, a prairie dog colony, but not actually using the colony. Although we cannot rule out the possibility that these species were using the colonies, we suggest that based on habitat affinities, many, if not most, of these 52 species were probably accidental. Because lists of species associated with prairie dog colonies have been used to justify conservation of prairie dogs, caution should be used when including potentially accidental and exotic species in lists of prairie dog associates.

Our evaluation of dependence highlights the considerable range in strength of association with prairie dogs for the 208 species. Life history information and expert review of species lists suggests that many purported associated species have a weak relationship to prairie dogs at best. We also stress that for most species, relationships to prairie dogs cannot be determined from available data. Even in studies in which data were available, sample sizes and geographic coverage were often small (Table 2). Considering that association with prairie dogs probably varies across habitats and species of prairie dog, extrapolation outside the geographic coverage of one particular study is tenuous. Further research is clearly needed to clarify the relationship of most of the 208 species to prairie dogs.

In summary, our review of both species richness patterns and assessment of strength of association suggests that the prairie dog's influence on vertebrate species richness may be lower than frequently asserted. Nevertheless, prairie dogs substantially contribute to biological diversity across their range because prairie dog colonies support a different composition of species than uncolonized areas (O'Meilia and others 1982, Agnew and others 1986, Mellink and Madrigal 1993). In addition, potentially dependent species such as black-footed ferrets, mountain plovers, burrowing owls, ferruginous hawks, and swift foxes have suffered population declines, and many either have, or are under consideration for, special protection under the Endangered Species Act (Samson and Knopf 1994). Because the long-term viability of declining dependent species may be compromised should prairie dogs continue to decline, management for prairie dogs will clearly benefit these species that are at risk.

Are Prairie Dogs a Keystone Species?

Paine's Keystone Species

To reevaluate the keystone role of prairie dogs, we first assess whether our revised prairie dog role is consistent with Paine's original concept of a keystone species whose "activities greatly modified species composition and physical appearance" and determined "the integrity of the community and its unaltered persistence" (Paine 1969). Our review indicates that nine vertebrate species may decline or disappear at a local scale, and in several cases at a landscape scale, if prairie dogs are eliminated. The black-footed ferret is apparently so specialized on prairie dogs that it does not persist where prairie dogs are eliminated. In addition, the continued reduction of prairie dog populations could hasten the demise of mountain plovers and burrowing owls, or decrease the abundance and distribution of the ferruginous hawk, golden eagle, swift fox, horned lark, grasshopper mouse, and deer mouse, diminishing biological diversity across prairie landscapes. Thus, it is not necessary to believe that prairie dogs have 208 associated species to conclude that they affect community integrity.

The disturbance activities of prairie dogs are akin to the disturbance role of the starfish (*Pisaster*) in the rocky intertidal that Paine used as a model of a keystone predator (Paine 1966, 1969). This disturbance role affects both species composition and ecosystem functions. Prairie dogs are not the only agents of disturbance in the Great Plains, but the scale at which they operate is unique. Prairie dogs aggregate into colonies that are sometimes quite dense and large, often persisting at a site over several decades. Their sedentary and colonial behavior tends to concentrate disturbance to a greater degree than the more dispersed and shorter duration disturbances caused by the actions of other

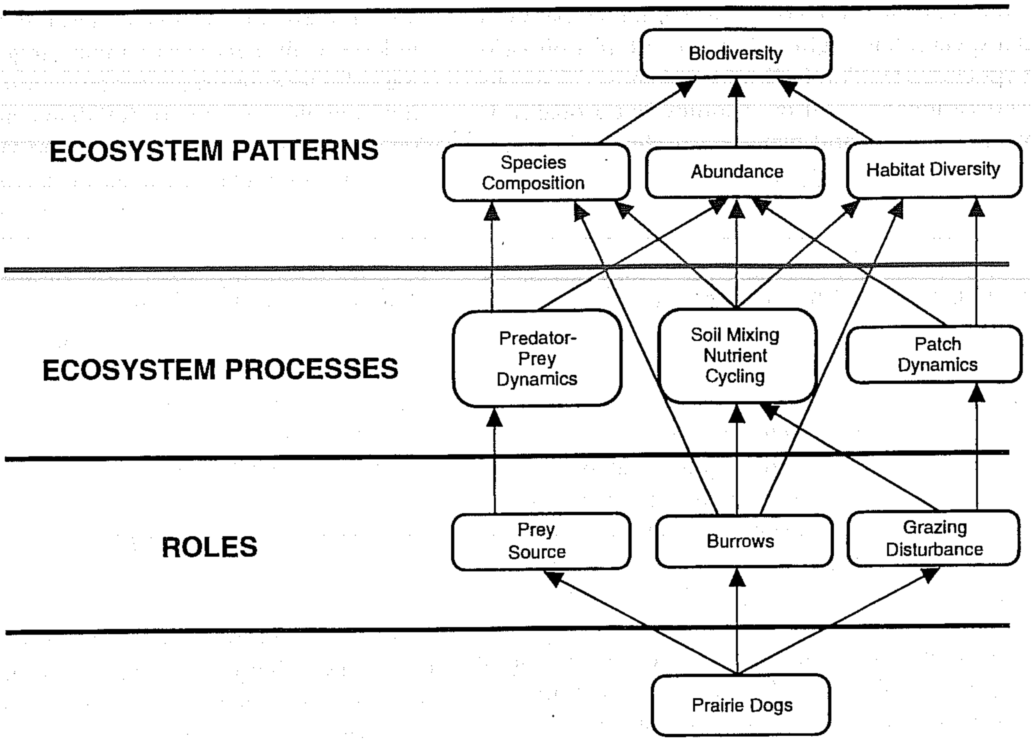

Figure 1. Dominant pathways by which prairie dogs affect ecosystem structure and function.

fossorial mammals, as well as more nomadic ungulates. The disturbance function of prairie dogs becomes even more critical in highly altered prairies that have lost natural disturbance regimes created by fire and large ungulate herds. Consequently, we conclude that prairie dog activities are important to ecosystem integrity and persistence. Thus, even though we found the magnitude of the prairie dog's role was sometimes overstated in the literature, it does meet Paine's qualitative definition of a keystone species.

Power's Keystone Species

Since Paine's original concept was developed, the term keystone has become rather loosely applied and its use in setting conservation priorities has been questioned (Mills and others 1993), leading to an attempt to clarify its definition (Power and others 1996). This new definition has two components: (1) a keystone species has a large overall effect on community or ecosystem structure or function, and (2) this effect is disproportionately large relative to its abundance (Power and others 1996). In addition, Power and others (1996) developed an equation for evaluating per capita effects that provides a quantitative framework for evaluating keystone status. In light of the new keystone definition, we evaluated whether the influence of prairie dogs on ecosystem processes and diversity patterns constitutes large overall effects and whether these effects are large relative to other species in prairie systems.

We begin by assessing whether prairie dogs have a large overall effect on ecosystem structure and function. Although prairie dogs do not consistently increase vertebrate and plant species richness at small scales, they do locally alter species composition and increase landscape-scale diversity by affecting the abundance and distribution of dependent species. In addition, they affect a number of ecosystem-level processes that, in turn, affect landscape heterogeneity and diversity. Individually, none of these functions is particularly large, but collectively they do have a pronounced effect on ecosystem structure and function (Figure 1).

To assess whether these effects can be considered large, we compare the overall impact of prairie dogs to other native herbivores in prairie systems. Prairies are also grazed by ground squirrels and historically were grazed by bison (Benedict and others 1996). Ground squirrels and pocket gophers provide burrows and also serve as prey, although their spatial distribution is typically more dispersed than prairie dogs. The magnitude of the impact of each prairie dog function probably matches or exceeds that of other Great Plains herbivores, but we suggest that none of the other species matches the diverse number of ways prairie dogs influence the system. Furthermore, keystone species

[e] Belovsky 1986.

typically function as either predators, prey, mutualists, or habitat modifiers (Mills and others 1993, Power and others 1996). Thus, prairie dogs differ from most conventional keystone species because they fulfill more than one function, acting as prey and modifying the habitat structure and dynamics in several ways. Therefore, we conclude that prairie dogs do indeed have a large overall impact in prairie systems.

To evaluate the second criterion (large effects relative to abundance), we evaluated per capita effects on an ecosystem trait. Operationally, calculation of per capita impacts has a number of difficulties (Power and others 1996). As is the case with most keystone species, experimental data are not available for prairie dogs. Despite this challenge, we conducted a preliminary comparison of per capita disturbance effects using data from Badlands National Park in South Dakota (Beckstead 1977). Black-tailed prairie dogs occupy approximately 12% of the park's 11,000-ha Badlands Wilderness Area, which also supports an intact guild of native ungulate herbivores (bison, mule deer, and pronghorn). Population levels of these species probably reflect historic levels. We estimated per capita primary consumption, standardized by biomass, for each of these four herbivores (Table 4). We also compared primary consumption per hectare. Due to higher basal metabolic rates, primary consumption per kilogram of body weight was greatest for prairie dogs. In addition, the sedentary and colonial behavior of prairie dogs concentrated their activities relative to the more nomadic ungulates; at observed densities, daily consumption per hectare by prairie dogs was at least an order of magnitude higher than any ungulate species. Even if the bison herd size were doubled, prairie dog consumption would still exceed cumulative ungulate consumption. These results indicate that standardized per capita effects of prairie dogs on ecosystem function may meet or exceed the impacts of other herbivores in the Great Plains. We conclude that existing data also meet the criteria of Power and others for keystone species.

Management Implications of Keystone Status for Prairie Dogs

We agree with previous conclusions that prairie dogs are a keystone species that should be targeted for conservation efforts. Prairie dogs have long been controlled on federal, tribal, state, and private lands, primarily at government expense, without any regard for their inherent values (Miller and others 1990). Because keystone status indicates that management for prairie dogs will benefit other species, it provides an important evaluation criterion for balancing two dominant and opposing management themes, prairie dog eradication and conservation. Indeed, keystone status has led public land managers to reevaluate widespread prairie dog eradication programs (Miller and others 1994). It also provides leverage for managers to protect prairie dog habitat when weighing management decisions among multiple uses of public lands and may help to offset the negative view of prairie dogs held by much of the general public.

Even though we agree that prairie dogs have important functions, we caution conservation proponents against overstating the role of prairie dogs. Protective measures for prairie dogs can be justified by existing data that clearly show the disproportionately large effects prairie dogs have on the health and functioning of prairie and shrub-steppe systems. Although dependent, and possibly opportunistic species, can benefit from prairie dog conservation, an inflated list of associated vertebrate species could mislead managers into the

BLACK-FOOTED FERRET-PRAIRIE DOG INTERRELATIONSHIPS

Raymond L. Linder
Leader, South Dakota Cooperative
Wildlife Research Unit[1], Brookings

Robert B. Dahlgren
Assistant Leader, South Dakota
Cooperative Wildlife Research Unit, Brookings

Conrad N. Hillman
Wildlife Research Biologist, U.S. Bureau
of Sport Fisheries and Wildlife, Rapid City, S. Dak.

The black-footed ferret (Mustela nigripes) has been accorded "endangered" status by the U. S. Bureau of Sport Fisheries and Wildlife since 1964. Discovery of ferrets in Mellette County, South Dakota, on a town of black-tailed prairie dogs (Cynomys ludovicianus) led to initiation of a study by personnel of the South Dakota Cooperative Wildlife Research Unit and the South Dakota Department of Game, Fish and Parks (Henderson et al. 1969). Continuing studies led to publications on ferret life history by Hillman (1968) and by Springer (1970); on parasites of the ferret by Boddicker (1968); on burrow systems of prairie dogs by Sheets et al. (1971); and on ferret food habits by Sheets and Linder (1969) and Sheets et al. (1972).

Ferret scats uncovered from burrows of the prairie dog were found by Sheets et al. (1971) to contain chiefly prairie dog remains (91 percent frequency) and remains of mice (26 percent frequency). Hillman (1968) reported that ferrets accepted live-tethered and dead prairie dogs, mice, cottontails, thirteen-lined ground squirrels, and birds placed near the prairie dog burrow they were inhabiting; he also reported that two ferret scats found contained only prairie dog hair and bones, and observed that ferrets had killed prairie dogs, chiefly underground. Henderson et al. (1969) reported that one ferret scat found consisted entirely of prairie dog hair and bones and reported

---

[1] Supported jointly by the South Dakota Department of Game, Fish and Parks; U.S. Bureau of Sport Fisheries and Wildlife; South Dakota State University; and The Wildlife Management Institute.

observations of ferrets taking prairie dogs, both dead and alive; they concluded that ferrets lived chiefly in prairie dog towns and depended largely on prairie dogs for their diet.

Since ferrets appear to depend on prairie dogs both for a home and for food, we conducted further studies toward an understanding of ferret-prairie dog relationships. Appreciation is extended to Donald K. Fortenbery, biologist, formerly assigned to ferret studies at Rapid City, for use of his files on sightings of ferrets. The Welder Wildlife Foundation, Badlands Natural History Association, and National Park Service supported early studies by the Unit. The Audubon Society supported work on prairie dog towns in Mellette County in 1972. We are grateful for the cooperation of Maurice E. Anderson, Acting State Supervisor, Division of Wildlife Services, Pierre, South Dakota, for making available records of the former U.S. Bureau of Biological Survey and those of the U.S. Bureau of Sport Fisheries and Wildlife.

METHODS

From June 8 - August 23, 1972, a study was conducted in Mellette County, South Dakota, which consisted of (1) ascertaining the attitudes of landowners toward prairie dogs and ferrets and (2) locating prairie dog towns and mapping and measuring a sample of them. Each rancher in the county was contacted and interviewed concerning locations of prairie dog towns on his land. After the interview, which was conversational, his attitude toward prairie dogs and ferrets that might influence possible ferret management programs was recorded.

Each prairie dog town reported was visited and plotted on a county map. A sample of 40 towns was randomly selected and visited for measurement and more detailed mapping. Depending on the size of the town, the topography on which it occurred, its shape, and its location in relation to natural features, it was mapped using either: 1) several transects paced off to bisect the town; 2) a closed transect by pacing; or, in one instance, 3) a closed-transect by automobile. Prior to survey, counts of prairie dogs above ground were made 2 or 3 times with either 7x50 binoculars or a 20X spotting scope. Weather conditions and time of day were noted at the time counts were made. Counts were averaged, and the average was compared with prairie dog activity curves previously obtained using the percentage of marked prairie dogs above ground under varying conditions and times of the day (Sheets 1970); this comparison yielded an estimate of the total prairie dogs inhabiting the town.

The random sample of 40 towns that were counted and measured was used to estimate the average size of prairie dog towns and the average population of prairie dogs in the county.

Ferret sightings published by Henderson et al. (1969) and Hillman (1971) were combined with those in the files of the Cooperative Wildlife Research Unit, designated as the repository for all ferret sightings in South Dakota since 1966. In addition, Donald Fortenbery, biologist, formerly with the U.S. Bureau of Sport Fisheries and Wildlife at Rapid City, made his file on ferret sightings available to us. Records and correspondence of the Biological Survey and the Division of Wildlife Services, Pierre, were made available and records pertaining to ferrets were extracted from them.

RESULTS

Ferret Distribution

The black-footed ferret is characteristic of the mid- and short-grass prairies. Hall and Kelson (1959) reported that its range nearly coincided with that of prairie dogs (genus Cynomys). It was found from Saskatchewan and Alberta on the north and to the south as far as Texas, New Mexico and Arizona. Henderson et al. (1969) reported that, during the century following discovery of the ferret (Audubon and Bachman 1851), its distribution decreased and that the decline in its numbers resulted from changing land use and control of prairie dogs by poison.

The abundance of the ferret in the past is not known. Because of its nocturnal habits, it is a difficult animal to observe. Except when young are on a prairie dog town, many nights of observation often fail to reveal the presence of a ferret even if one is there. It has been commonly assumed that the ferret was never abundant (Cahalane 1954); however, a biological assistant with the U. S. Bureau of Biological Survey reported that "extensive inquiry brings out the fact that [black-footed] ferrets are not uncommon on the [Indian] reservations of this state [South Dakota] and in certain counties" (monthly report for August dated Sept. 25, 1923).

The following ferrets were mentioned in U.S. Bureau of Biological Survey reports filed at Pierre, South Dakota:

Year	Total Ferrets	Ferrets by Month Month	 Number	 How taken
1917-22	None reported			
1923	1	September	1	trapped (Pine Ridge)
1924	10	September	1	trapped
		October	6	trapped
1925	11	March	2	poisoned
		July	1	trapped
		August	1	trapped
		September	1	trapped
1926	4			
1927	7	March	2	trapped
		April	2	trapped
		August	1	trapped
1928	10	February	1	trapped
		March	5	trapped
		May	1	trapped
1929	1			
1930-39	None reported			

Month and method of capture were not mentioned for all ferrets reported.

With the exception of the ferret taken in September of 1923, the records did not indicate from which area of the state ferrets were taken. A few of the above ferrets were probably placed in the U.S. National Museum and data on them were published by Henderson et al. (1969); however, these authors reported records on only seven ferrets from 1923-29. Since 44 ferrets were reported by men working in ferret-prairie dog range during this 7-year period, ferrets must have been, if not abundant, at least "not uncommon".

Records of ferret sightings in South Dakota were published by Henderson et al. (1969) and by Hillman (1971). These published records, along with those in Table 1, were combined to show the distribution of ferrets in South Dakota (Fig. 1). Ferrets have occurred chiefly in western South Dakota. The greatest number of ferrets were seen in Mellette County, principally because of a concentrated effort to locate

* National Park Service memorandum dated August 3, 1961, reporting on progress of black-footed ferret study during July, 1961, signed by Seasonal Ranger Naturalist John D. Hunter (courtesy Badlands National Monument).

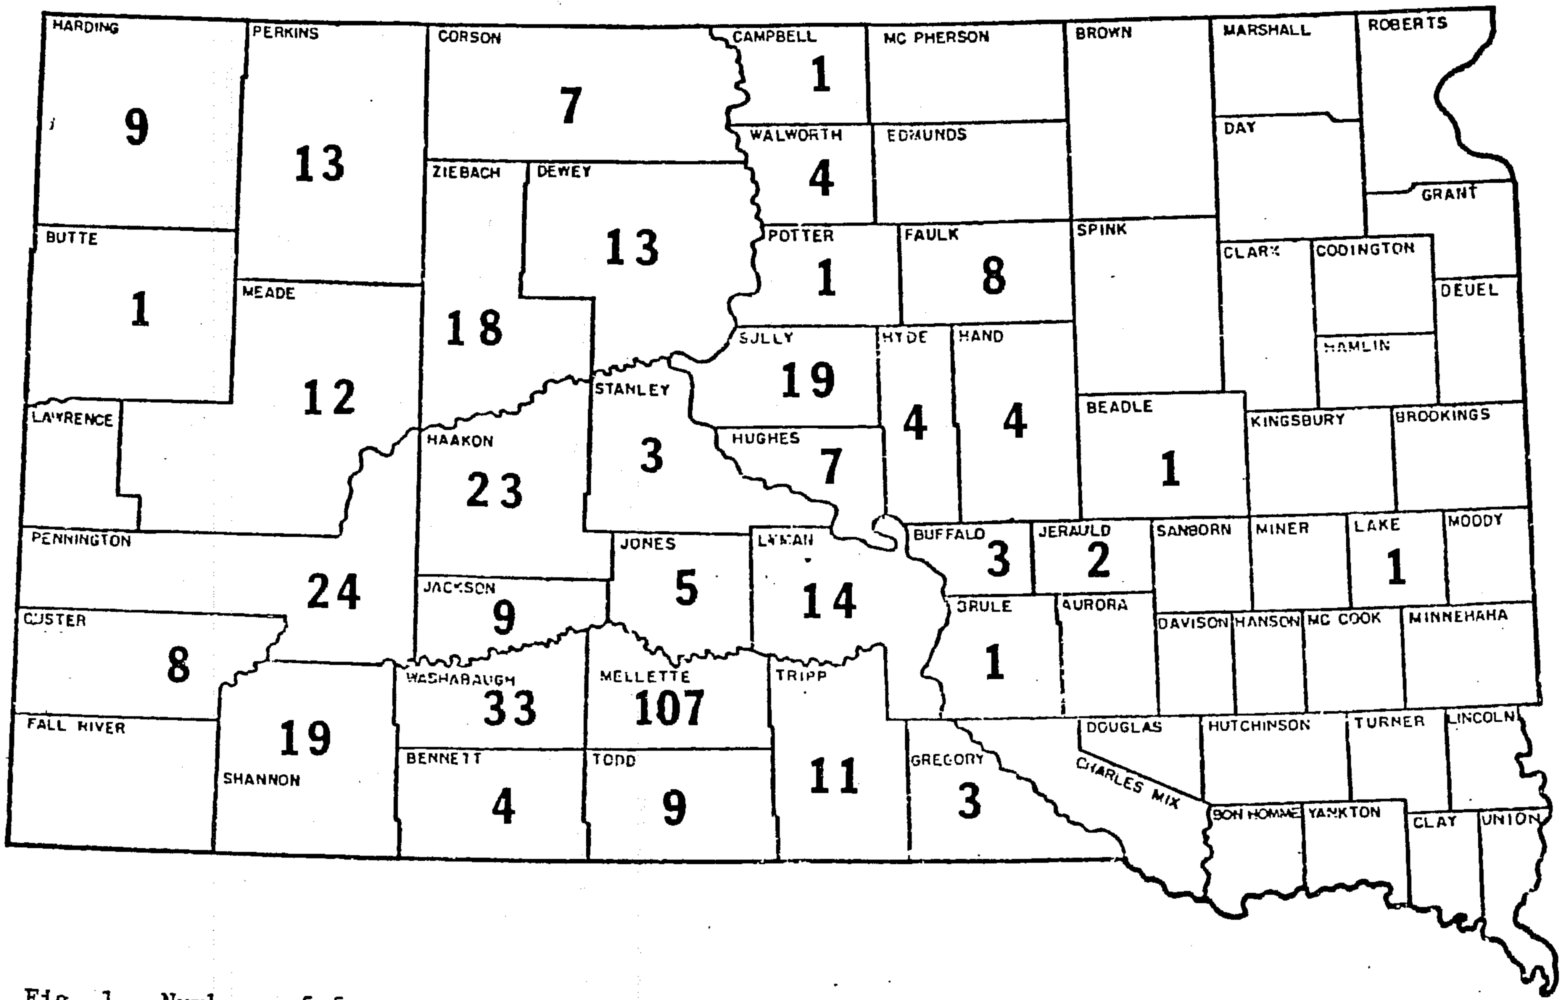

Fig. 1. Numbers of ferrets seen by county in South Dakota, taken both from published and unpublished sources, 1889-1972.

them there since studies by the Unit were begun in 1964. More ferrets were seen in Mellette and Washabaugh Counties than in other counties of the state even prior to 1964. These counties probably represent the area of greatest ferret density in the state.

Prairie Dogs

Several workers have reported an abundance of prairie dogs in North America in the past. Seton (1928) reported that there were probably five billion black-tailed prairie dogs in North America. Merriam (1901) reported there were 400,000,000 prairie dogs on one Texas colony at one time; Seton estimated 800,000,000 in Texas.

Examination of U.S. Biological Survey records for the years 1918 to 1940 gives some indication of prairie dog numbers and control efforts in South Dakota during that period. A Predator Animal Inspector for the U.S. Bureau of Biological Survey, H. R. Wells, estimated that there were 1,756,720 acres of prairie dogs in South Dakota in 1923. Of those acres, 1,283,000 were on private land and 473,720 acres were on public land. This was reduced to an estimated 45,000 acres in the state in 1967 (Henderson et al. 1969).

Control efforts on prairie dogs in South Dakota were intense from 1918 to 1925 (Fig. 2). Intensive control effort was reported for all counties, and in many counties, prairie dogs were considered to have been exterminated.

Control was slackened from 1925 to 1930, partly due to lack of funds, and partly because the emphasis of control was shifted to other rodents such as Norway rats (_Rattus norvegicus_), flickertails (_Citellus richardsonii_) and pocket gophers (_Geomys bursarius_ and _Thymomys talpoides_). These rodents occurred in the cultivated areas of the state and were then considered to be more important than those pests occurring in the rangeland of western South Dakota.

In 1930, effort was again directed toward control of prairie dogs. At that time, many counties reported that prairie dogs were as numerous as before the intensive campaigns began in 1918. Control campaigns using strychnine were initiated during the drought years of the 1930's. Many government programs developed during the depression years were used to control prairie dogs: W.P.A., C.C.C., Indian Emergency Conservation Work, Forest Service in Farm Forestry Programs, Emergency Relief Administration, Resettlement Administration, and Forest Emergency Conservation Work. From 1932 to 1939, over 1,000,000 acres of prairie dog lands were treated. Every county within the prairie dog range in the state reported control efforts. Prairie dogs were reported to have been exterminated in 30 counties (Fig. 3). One report listed all of South Dakota east of the Missouri River as being free of prairie dogs.

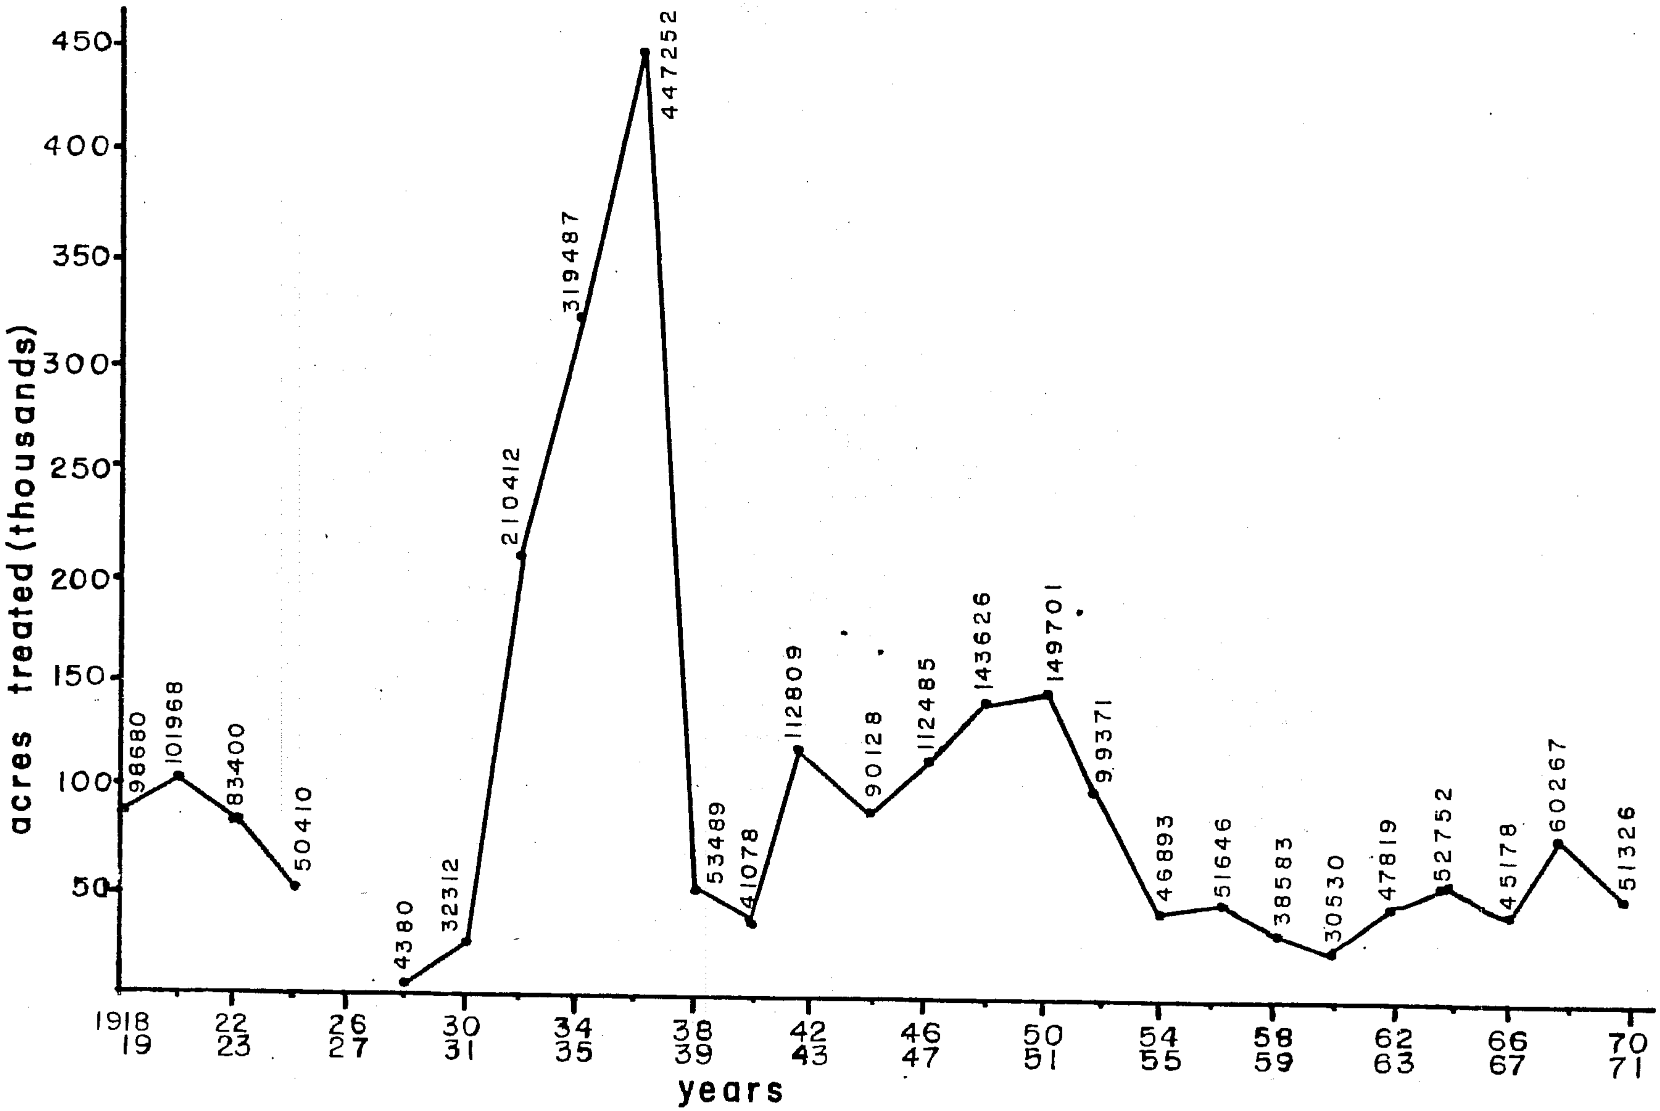

Fig. 2. Acres of prairie dog towns treated with poison bait, South Dakota, 1918-71.

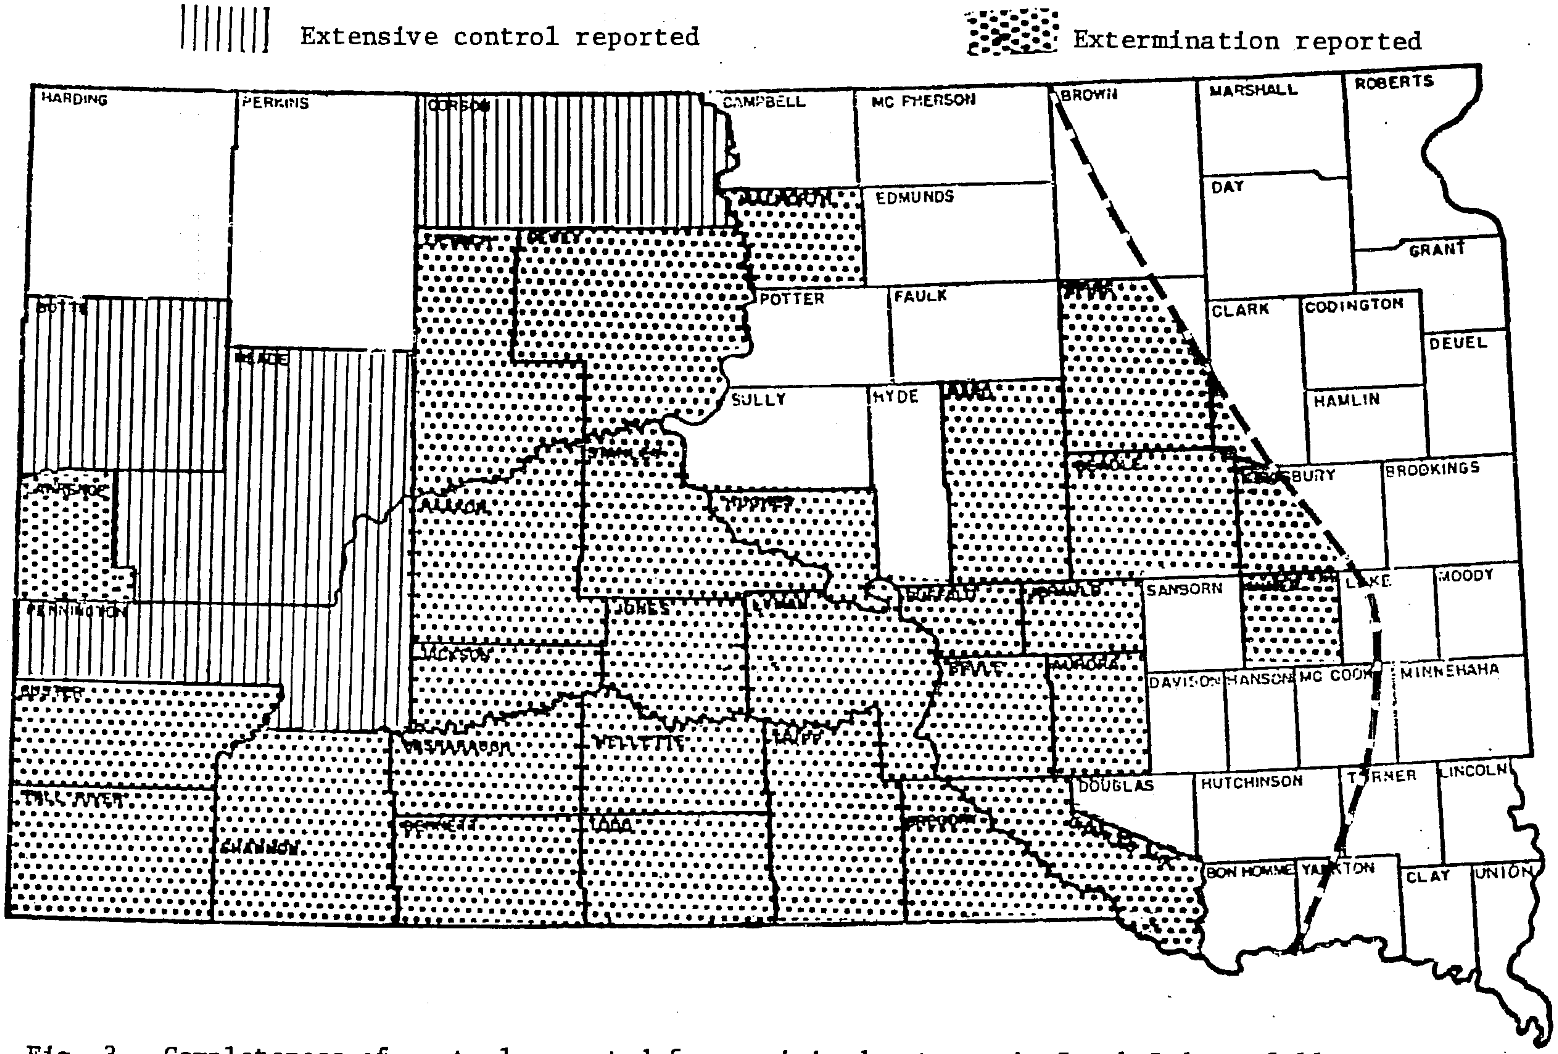

Fig. 3. Completeness of control reported for prairie dog towns in South Dakota following the poisoning campaign of the 1930's. Broken line represents the eastern edge of the prairie dog range.

These extensive poisoning campaigns may have been important in reducing numbers of ferrets as well as prairie dogs. When control was less than complete in a prairie dog town, prairie dogs increased rapidly; this evidently happened after the early 1920's and again following the late 1930's. Control since that time has kept their numbers at a low level. The quantitative effect of extensive poisoning on ferret numbers is not known; however, ferrets have been reported over about the same area in South Dakota in the last 10 years as they occurred in formerly.

Prairie Dogs and Ferrets in Mellette County

Students and biologists assigned to the ferret studies have seen 38 young ferrets in 11 litters and 26 adults since 1964 in Mellette County. These and other observers reported a total of 90 ferrets at different locations in the past 10 years in the county. Of course, only a small proportion of the ferrets probably were seen and/or recorded. Much of the time spent in attempting to make ferret observations was on the Carr (now Nielsen) Ranch about 12 miles west of White River. Other efforts were centered in the southwest and western portion of the county; relatively little time was spent east of White River. However, ferret sightings were made in all parts of the county.

Numbers of prairie dogs have varied considerably in the county. In 1929, an employee of the U.S. Biological Survey estimated that there were 47,000 acres of prairie dog towns in Mellette County. Henderson et al. (1969) estimated 2,000 acres of prairie dog towns in the county for 1967. During the past summer, we attempted to locate all prairie dog towns in the county. We found 151 towns (Fig. 4); their average size was 21 acres. We estimated that there were 239 prairie dogs per town, for a population of 36,000 in the county.

The prairie dog towns in Mellette County (Fig. 4), totaling about 3171 acres, appear to be maintaining a ferret population. Ferrets have been observed in most parts of the county. In the southwest region of the county, there is considerable cropland with small prairie dog towns interspersed in the pastures. For several consecutive years, ferrets have been observed there. In the area south and west of White River on the Carr (now Nielsen) Ranch, ferrets were studied from 1966 to 1969. There was a litter each of 3 years on a 107-acre town and one other litter on a 64-acre town on the ranch. This region is all grassland and badlands type with few prairie dog towns, but the towns are large. We have also seen ferrets in the eastern part of the county, where more land is used for crops. Some observations of ferrets were made on small towns (under 10 acres) and some on larger towns.

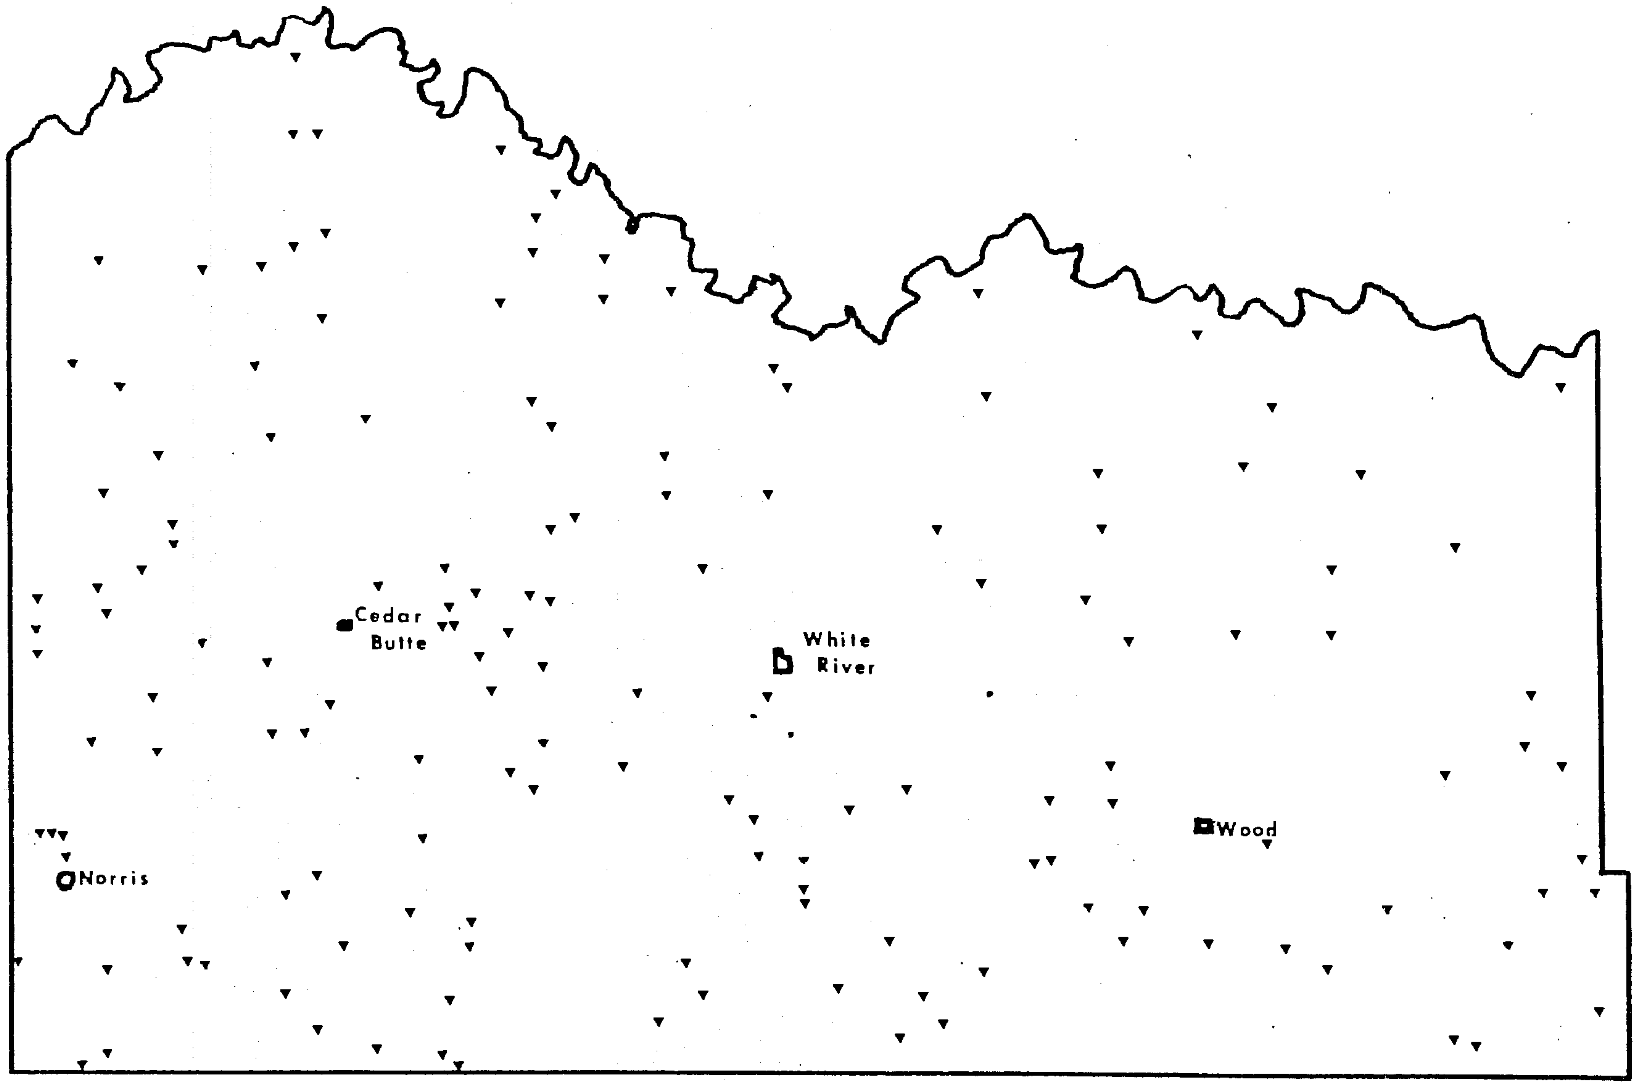

Fig. 4. Distribution of 151 active prairie dog towns in Mellette County, South Dakota, 1972.

MANAGEMENT

Because the ferret is chiefly dependent upon the prairie dog for shelter and diet, management in favor of prairie dog populations in ferret-occupied areas is management in favor of ferret populations.

Proposals for management of ferrets have been suggested by previous workers. Henderson et al. (1969) listed 10 recommendations. Included in those recommendations were (1) "explore all feasible means of retaining adequate numbers of prairie dogs and ferrets on both public and private lands," (2) "experiment with transplanting and releasing ferrets into areas where prairie dogs are protected," and (3) "develop materials for prairie dog and other animal control that will not poison ferrets." The Trail (published by the National Audubon Society and the North Central Audubon Council, 1972) editorialized that a "prairie dog bank" might be in order, following the same pattern as the "water bank" or the "soil bank."

In interviews with Mellette County ranchers, 19 percent were against having any prairie dogs, 19 percent were against any poisoning of prairie dogs, and 62 percent of them stated they would like to have prairie dog towns if they could keep the towns from becoming too large. Thus, techniques to control prairie dog numbers that would be safe for ferrets are needed. Such a technique might be the use of reproductive inhibitors. Preliminary work by a graduate student of the Unit indicates that this may be a useful technique (Pfeiffer 1972), but further work needs to be done.

A transplanting program or a captive-breeding program for restocking ferrets might be feasible. One of the most valid objections to any restocking program is that restocking is usually not effective because the habitat for the species is absent or curtailed. However, for the ferret, much habitat is available in the form of prairie dog towns in the western half of South Dakota. There are areas in South Dakota where prairie dogs occur but where ferrets have not been reported, even after extensive searches.

We have managed game species for years by developing or preserving habitat; some of these game management techniques should be useful for ferrets. Gates (1970) proposed that wetlands interspersed in the farmlands be preserved for pheasant habitat. Hamerstrom et al. (1957) recommended a "scatter-pattern" of 40 acres per section managed for prairie chickens in Wisconsin where that species was endangered. A scattered distribution of prairie dog towns may be important to the ferret.

In Mellette County there are approximately 3200 acres of prairie dog towns. It appears that this many acres of prairie dog towns has been adequate as habitat and food supply for ferrets. These prairie dog towns could be administered similar to wetlands in present waterfowl programs; instead of "Waterfowl Production Areas" they could be "Ferret Production Areas."

Prairie dog towns could be preserved by purchase, lease or easements. An estimate of the value of grazing land in Mellette County is about $50.00 per acre (Westin et al. 1971). Thus, the purchase price of land occupied by prairie dogs would be $160,000. Current lease value of grasslands in the county is about $3.00 per acre, so leasing the prairie dog towns would cost $9,600 annually. Easements would be even less in cost.

Easements of prairie dog towns would perhaps be the most practical method. With an easement to preserve prairie dog towns on his land, the rancher could continue grazing the towns in a normal manner. Grazing by cattle is probably beneficial in maintaining the towns. It would be necessary to stipulate in the terms of the easement that prairie dogs could not be eliminated or controlled by using any methods that might be detrimental to ferrets. Shooting on towns could be permitted and would furnish sport to the rancher and his friends. With an easement arrangement, the rancher could be compensated for an increase in size of dog towns if he chose not to control their expansion.

By obtaining an easement on prairie dog towns in an area where ferrets exist, we would have some assurance that ferrets could be maintained until further research could be used to answer some of the questions involved in ferret management. One of the prime objectives of research should be to determine the sizes, numbers, and spatial distribution of prairie dog towns necessary to maintain ferret populations. Such research would be important for possible expansion of the range of the black-footed ferret into areas now occupied by the prairie dog in North America.

****

In answer to questions, Dr. Linder added that the availability of ferrets for transplants is still uncertain. He said that Patuxent has been working with domestic ferrets in preparation for attempts to raise black-footed ferrets in captivity.

Contents

Acknowledgments

The Symposium on the Status of the Black-footed Ferret and Its Habitat, held January 28–29, 2004, in Fort Collins, Colo., and the resulting proceedings contained herein would not have been possible without the dedicated efforts of numerous individuals and agencies. Financial support for the meeting itself and for publication of this volume was provided by Aaron and Gretchen Clark of the Black-footed Ferret Recovery Foundation, by the U.S. Fish and Wildlife Service, and by the U.S. Geological Survey. Sandi Godbey, ably assisted by Jenny Benson, Matt Dunfee, Darren Long, Noe Marymor, Adam Phillips, Adrianna Siniawski, and Ashley Skeen, attended to the infinite variety of details that make a meeting run smoothly. We gratefully acknowledge Dr. Andrew Dobson, Princeton University, Department of Ecology and Evolutionary Biology, for the keynote address, as well as the assistance of Della Garelle, Mike Lockhart, Bill Van Pelt, and Chris Brand, who served as session moderators. We thank Mike Lockhart, Paul Marinari, and Julie Kreeger for hosting a field trip to the National Black-footed Ferret Conservation Center, which at the time of the symposium was under construction but is now a fully functioning facility. We are indebted to Dale Crawford, Delia Story, Jennifer Shoemaker, and especially Dora Medellin for their able assistance in preparing the text and graphics for publication and to Heather Branvold, Patricia Mendoza, and Dale Crawford for graciously allowing us to use their artwork. Finally, we wish to thank the many organizations and countless individuals who have contributed to the Black-footed Ferret Recovery Program. While space does not allow us to mention them individually, it is obvious that neither the symposium nor this volume would have been possible without their unflagging efforts on behalf of one of North America's most engaging creatures.

Dedication

In the period between January 2004, when this symposium took place, and publication of the proceedings presented here, partners in the Black-footed Ferret Recovery Program suffered enormous personal and professional losses through the deaths of Tom Thorne, Beth Williams, Bill Russell, and Stan Anderson.

Tom and Beth, a husband and wife team of professional veterinarians and wildlife biologists, were killed in a traffic accident on their way home to Laramie, Wyo., on December 29, 2004. Both Tom and Beth were responsible for much of the original recovery program leadership and were deeply involved in all elements of black-footed ferret management and research. Their expertise and many notable scientific contributions significantly advanced our knowledge and capabilities related to black-footed ferret captive breeding, disease risks and management, vaccine efficacy and safety, and reintroduction.

Bill Russell died at Ivinson Hospital in Laramie on August 16, 2005. Bill was a Professor of Animal Science at the University of Wyoming for 25 years and was the official Black-footed Ferret Species Survival Plan® studbook keeper and genetic advisor for many years. Bill provided invaluable advice and recommendations on captive black-footed ferret management and breeding.

Stan Anderson died at his home in Laramie on September 1, 2005, following an extended illness. Stan started the University of Wyoming Cooperative Fish and Wildlife Research Unit in 1980 and served as a graduate advisor for many biologists who obtained advanced degrees studying various aspects of prairie dog conservation and black-footed ferret recovery.

These proceedings are dedicated to the memory and accomplishments of these long-time ferret recovery advocates, scientists, advisors, administrators, and mentors. The loss of these fine individuals leaves a substantial void in the institutional knowledge and foundation of the Black-footed Ferret Recovery Program and in the wildlife conservation community as a whole. They will be deeply missed, but their legacy will endure.

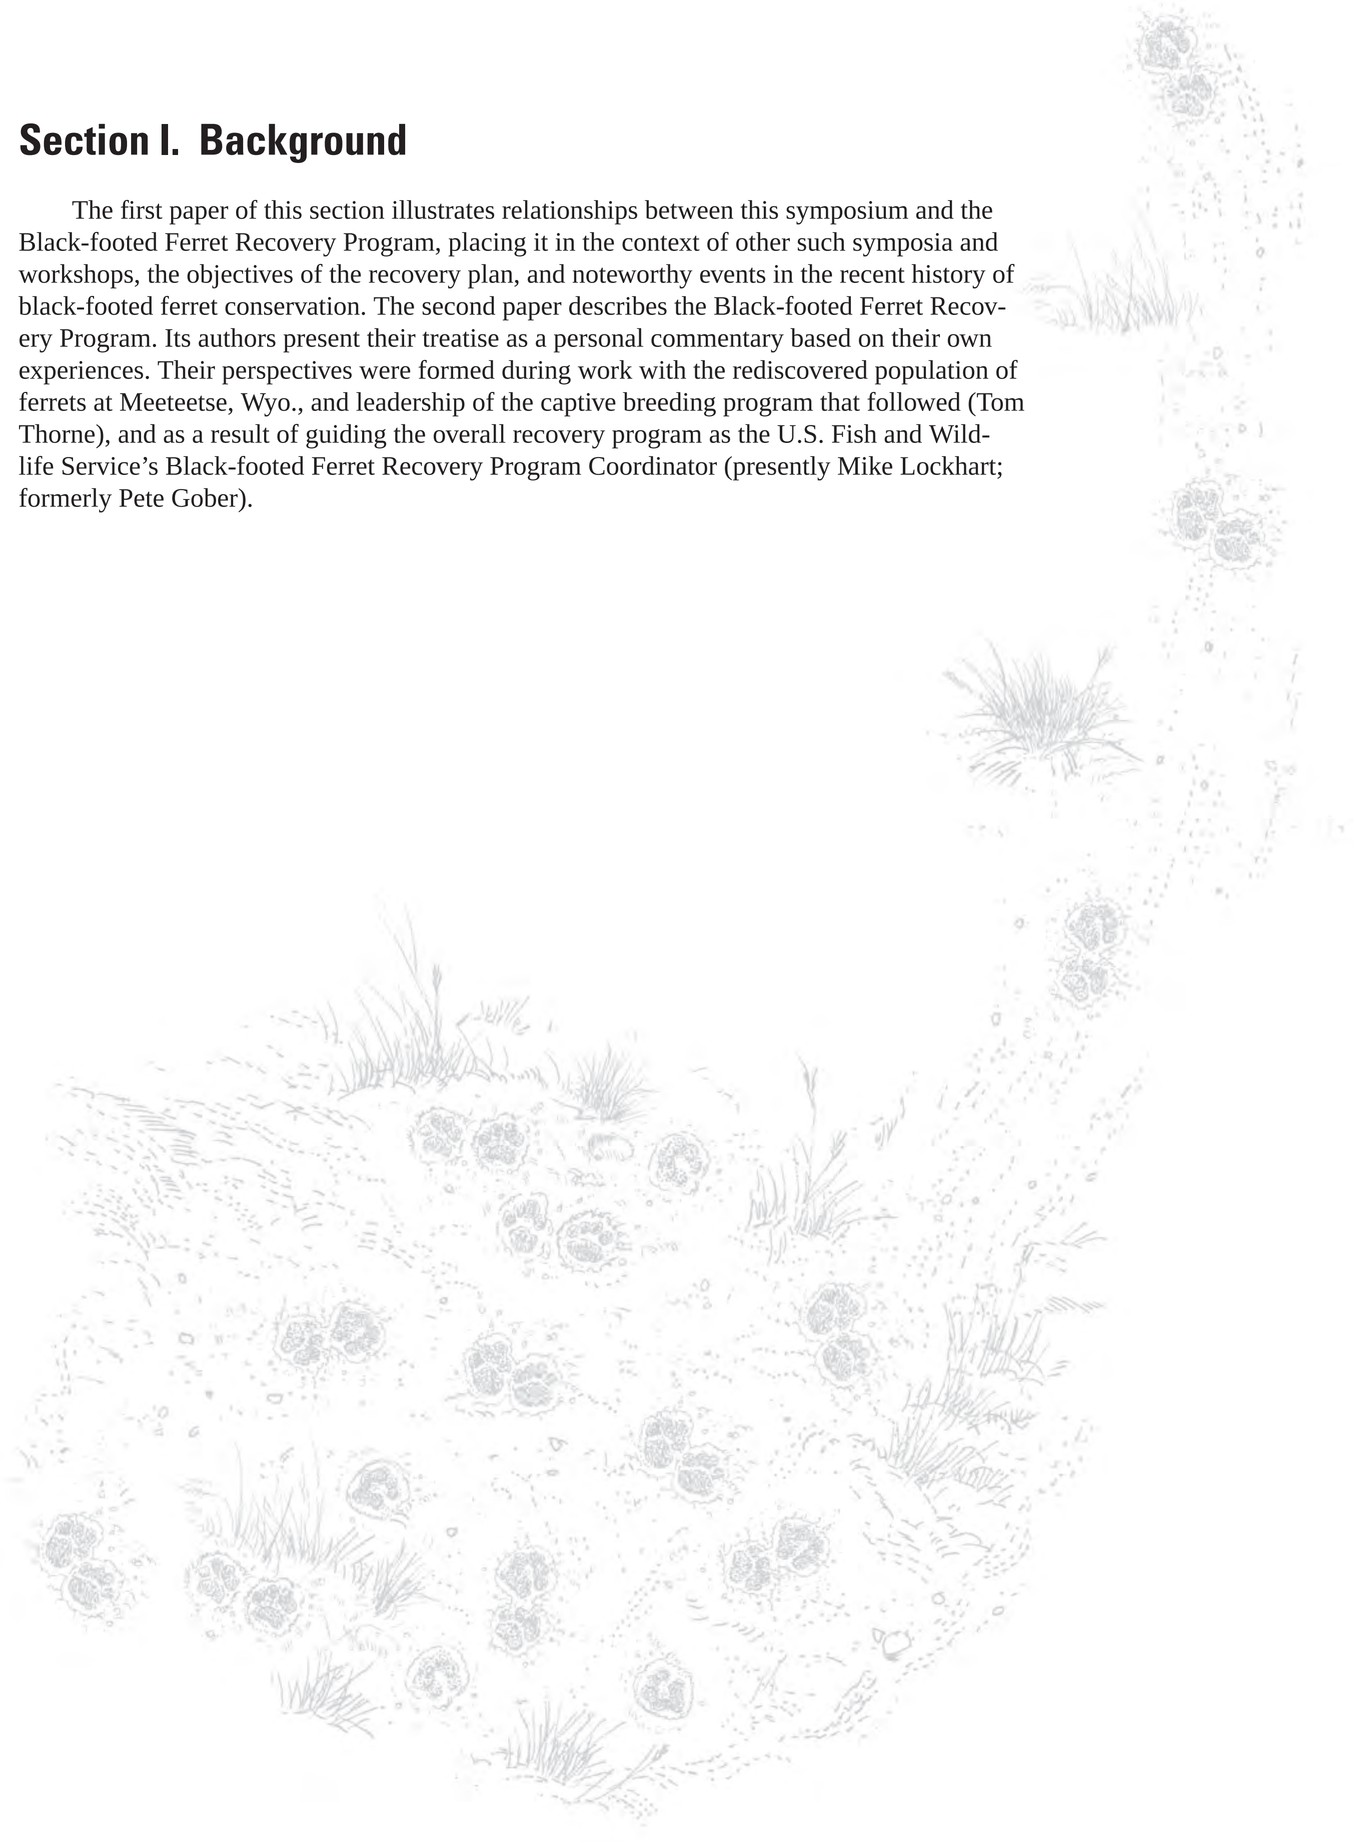
Section I. Background

The first paper of this section illustrates relationships between this symposium and the Black-footed Ferret Recovery Program, placing it in the context of other such symposia and workshops, the objectives of the recovery plan, and noteworthy events in the recent history of black-footed ferret conservation. The second paper describes the Black-footed Ferret Recovery Program. Its authors present their treatise as a personal commentary based on their own experiences. Their perspectives were formed during work with the rediscovered population of ferrets at Meeteetse, Wyo., and leadership of the captive breeding program that followed (Tom Thorne), and as a result of guiding the overall recovery program as the U.S. Fish and Wildlife Service's Black-footed Ferret Recovery Program Coordinator (presently Mike Lockhart; formerly Pete Gober).



The Symposium in Context

By Dean E. Biggins[1]

The black-footed ferret (*Mustela nigripes*) is a member of the weasel family (Mustelidae) and is closely related to the Siberian polecat (*M. eversmannii*) of Asian steppes and the European polecat (*M. putorius*). Compared to its relatives, the black-footed ferret is an extreme specialist, depending on the prairie dogs (*Cynomys* spp.) of North American grasslands for food and using prairie dog burrows for shelter. The black-footed ferret's close association with prairie dogs was an important factor in its decline. Prairie dogs were regarded as an agricultural pest as human settlement progressed westward, and they became important hosts for plague as that disease colonized eastward from its sources of introduction on the west coast. Prairie dog numbers were dramatically reduced by poisoning, cropland conversions, and plague during the first half of the 20th century, and black-footed ferret populations declined precipitously. The black-footed ferret was included on the first lists of endangered species, and its status was precarious by the time the Endangered Species Act of 1973 was passed. Its rebound from a low point of 10 known individuals in spring of 1985 (Biggins and others, 2006) is impressive, but the species is not yet "recovered" in either the biological or legal sense (for further details, see Lockhart and others, this volume).

Conservation activities to assist black-footed ferrets have extended through the past five decades. Included in those activities were three previous workshops and a symposium organized to facilitate interchange of ideas and information. The contents of their published proceedings illustrate changes in emphasis regarding issues important to black-footed ferret recovery. Placing these meetings in a chronological context of major events in ferret conservation (fig. 1) helps to explain motives for convening them and content of the papers, and provides context for the current volume.

The first workshop on black-footed ferrets and prairie dogs (Linder and Hillman, 1973) focused primarily on the rangewide status of the ferret and its prairie dog habitat, with

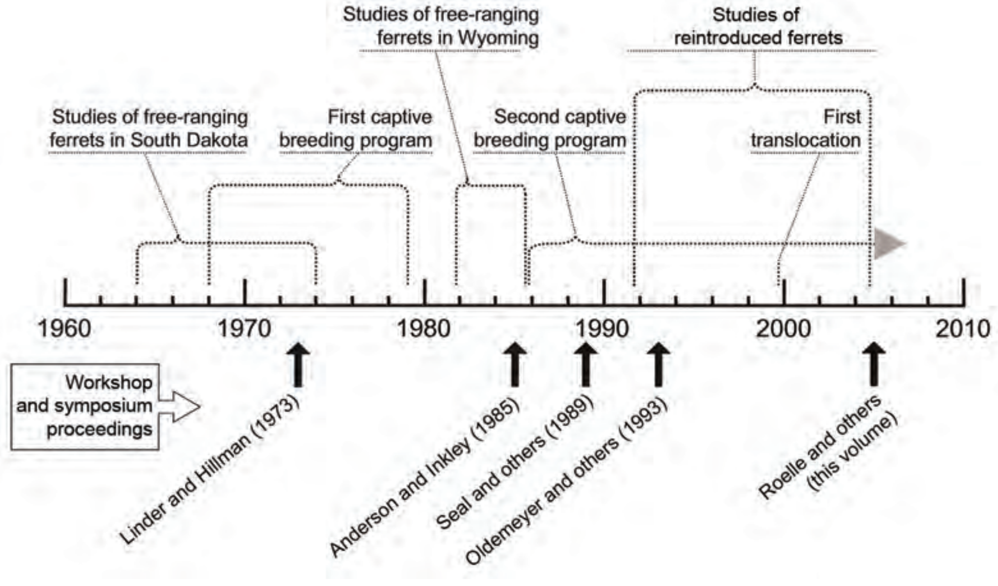


Figure 1. Timeline relating recent symposia and workshops to noteworthy events and periods in black-footed ferret (*Mustela nigripes*) research and recovery.

a single paper summarizing new information on the biology of the ferret. Despite 10 years of research on the black-footed ferret in South Dakota (fig. 1), Ray Erickson concluded that it remained "one of the least well known of all of the endangered mammals of the United States" (Erickson, 1973, p. 156). Rumors began circulating in the late 1970s that the black-footed ferret was extinct, but these contentions were short-lived because of the discovery of a population of ferrets near Meeteetse, Wyo., in 1981 (Biggins and others, 2006).

The second workshop on black-footed ferrets (Anderson and Inkley, 1985) occurred near the end of a rather brief period of intensive research on the Meeteetse population of ferrets and after the first attempt to captive breed South Dakota ferrets at the U.S. Fish and Wildlife Service's (now U.S. Geological Survey's) Patuxent Wildlife Research Center in Maryland (fig. 1). A single paper in that workshop was devoted to captive breeding, summarizing the failed Patuxent attempt but prophetically predicting success if the venture were to be repeated with ferrets from the Meeteetse population (Carpenter, 1985). The proceedings had a wide variety of other papers on the status of prairie dogs and ferrets, institutional and procedural issues, searches for more ferrets, and research needs. Six papers summarized original field research, much of which was conducted on the Meeteetse population. By summer of 1985, 10 months after the workshop, plague caused extensive declines in the Meeteetse prairie dog population, canine distemper was discovered in the ferrets, and the ferret population plummeted. These events caused an abrupt end to field research on ferrets and forced the beginning of the second captive breeding program following emergency rescue of the remaining animals. Carpenter's (1985, p. 12.11) admonition (presumably motivated in part by his Patuxent experience) to avoid the "tendency to initiate propagation programs as a last resort, when few animals are available for captive breeding" could not be heeded. Research at Meeteetse also served as the primary motivation for publication of a second collection of black-footed ferret papers the following year as number 8 of the Great Basin Naturalist Memoirs (Wood, 1986), although that volume was not the result of a symposium or workshop.

The third workshop, held in 1986, was conceived primarily in response to information needs for the newly developing second effort to maintain and produce black-footed ferrets in captivity (fig. 1). It blended developing theories in conservation biology with existing biological information on ferrets and polecats. This workshop resulted in a book (Seal and others, 1989) with chapters covering systematics, population biology, reproduction, captive propagation, and conservation.

The fourth meeting was a symposium convened in the summer of 1989. Although the captive breeding program had a tenuous beginning (Biggins and others, 2006; Lockhart and others, this volume), evidence predicting ultimate success had emerged by 1988, and thoughts were turning toward planning for reintroduction. Reports in the proceedings (Oldemeyer and others, 1993) focused primarily on habitat for reintroduction of ferrets. Plague received increased recognition as an ominous threat to ferret habitat, with several papers dedicated to discussion of that disease.

The symposium culminating in the papers presented herein was held on January 28–29, 2004, in Fort Collins, Colo. It had been more than 10 years since the previous symposium, and much new information on the biology of the black-footed ferret had been accumulated. Many of the papers published here resulted from information collected as captive breeding became more efficient and as black-footed ferrets were released back into native habitats (fig. 1). The symposium was organized into sections based on the principal topics in the stepdown outline of the Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988). The relationship between the recovery plan and the papers of this symposium illustrates that work is following a somewhat orderly progression guided by principal topics in the recovery plan. A brief description of that relationship introduces each section of this volume.

This volume and the five that preceded it, including proceedings from the three workshops and the symposium, plus the Great Basin Naturalist volume (Wood, 1986), cover a broad spectrum of work on prairie dogs and black-footed ferrets. Although these volumes certainly are not exhaustive in their coverage of ferret and prairie dog research and conservation activities, they collectively provide a solid foundation for future conservationists working with ferrets and chronicle a long-term recovery program for one of North America's most endangered vertebrates.

A Historical Perspective on Recovery of the Black-footed Ferret and the Biological and Political Challenges Affecting Its Future

By J. Michael Lockhart,[1] E. Tom Thorne,[2] and Donald R. (Pete) Gober[3]

Abstract

This paper is a personal commentary by the authors on the background and historical development of the Black-footed Ferret Recovery Program. The black-footed ferret (*Mustela nigripes*) was recognized as imminently endangered in the original Endangered Species Act and has a recovery history accentuated with near catastrophes and remarkable successes. In this paper, we examine the species' near demise, wild black-footed ferret populations, captive breeding efforts, and attempts to restore ferret populations into native habitats. We provide our personal perspectives on many lessons learned during these program stages, the social and political factors affecting species recovery, past and present biological obstacles, and insights relevant to the future of the species.

Keywords: black-footed ferret, captive breeding, endangered species, *Mustela nigripes*, recovery, reintroduction

Introduction

Rather than a technical presentation of data or a literature review, this paper is a personal commentary on historical aspects of the Black-footed Ferret Recovery Program. We offer our recollections and observations only as reflections of our own experiences. We acknowledge that many people contributed to black-footed ferret (*Mustela nigripes*) conservation over this period and that others may view program events and our conclusions differently; however, we submit that our unique positions of program responsibility over the years provide broad perspectives that others not directly involved in day-to-day ferret recovery, or involved in limited areas, may not have gained.

Collectively, as representatives of lead agencies responsible for ferret recovery, we have been directly involved in ferret conservation matters on a daily basis from 1981 to the present. The Wyoming Game and Fish Department (WGFD) was a primary participant in ferret recovery both in the field and in captive breeding from 1981 to 1996 and remains active in reintroduction and program planning activities today. The U.S. Fish and Wildlife Service (FWS) has been involved with ferret conservation since before the species was originally listed as endangered in 1967. Moreover, FWS has been directly involved with captive breeding since 1996 and has coordinated all other recovery activities since that time. In addition, FWS has investigated the likely effects of habitat loss on ferrets as a result of the decline of its principal prey—prairie dogs (*Cynomys* spp.).

In this paper, we discuss ferret conservation activities related to wild population management, captive breeding, and reintroduction into the wild. In particular, we address the significant biological, political, and social issues that affected species recovery. We focus only on the major highs and lows of ferret recovery as we view them; we defer the many important details to other participants in this symposium. Additionally, we characterize our observations of various efforts as successes, failures, or lessons learned. Finally, we provide recommendations linked to these conclusions that may contribute to future recovery of ferrets and perhaps other endangered species.

The opinions and recommendations presented in this paper are those of the authors and do not represent official positions of either the FWS or the WGFD. We also wish to acknowledge the extraordinary dedication, hard work, and contributions accomplished by the many State, Federal, tribal, zoo, and conservation organization partners on behalf of black-footed ferret recovery. Overall program success is the result of enormous efforts by these many program cooperators.

Management of Free-ranging Populations

Ferrets received little attention until the species was listed as endangered in 1967, one of several species to be designated under the first version of the Endangered Species Act (ESA). Early accounts, from Audubon's description of the type

specimen in the 19th century to anecdotes from rodent control personnel in the mid-20th century, largely treated the species as a novelty. Its secretive and nocturnal lifestyle in remote parts of western North America assured relative anonymity. Conversely, the ferret's principal prey received much more attention: prairie dogs were regarded as vermin, competitors with the agriculture industry, and impediments to western settlement. Accordingly, prairie dog populations were targeted for destruction, and decades of eradication efforts significantly impacted populations of prairie dogs and ferrets, the prairie dog's most highly specialized obligate predator.

Five species of prairie dogs occur in North America. Three of these species cover most of the collective prairie dog (and ferret) historical range: the black-tailed prairie dog (*C. ludovicianus*), the white-tailed prairie dog (*C. leucurus*), and the Gunnison's prairie dog (*C. gunnisoni*). No documented occurrence of ferrets has been linked to either the Utah prairie dog (*C. parvidens*) or the Mexican prairie dog (*C. mexicanus*). These two species have ranges that are relatively small and disjunct from those of the other three prairie dog species. Black-tailed prairie dogs occurred over the largest expanse of land (approximately 160 million ha), from southern Canada to northern Mexico between the 98th meridian and the Rocky Mountains. White-tailed prairie dogs and Gunnison's prairie dogs occurred over approximately 80 million ha to the west of the range of the black-tailed prairie dog. Perhaps 10–20 percent of the range of all of these prairie dog species was physically occupied before western settlement. The actual location of prairie dogs varied with topography, soils, rainfall, fire, bison (*Bison bison*) activity, and other factors. Regardless of the dynamics of these important and variable biological and ecological phenomena, it is obvious that ferrets had an enormous habitat base, and many thousands undoubtedly existed across the landscape.

Ferret populations declined over millions of hectares of occupied prairie dog habitat for three principal reasons. First, a major conversion of native prairie to cropland began late in the 19th century, continued steadily through the Dust Bowl years of the 1930s, and to a lesser extent continues today. Approximately one-third of black-tailed prairie dog potential habitat was rendered useless for prairie dogs by cropland conversion. In comparison, far less of the available habitat of white-tailed and Gunnison's prairie dogs was physically lost to land conversion because, outside of riparian corridors and proximate irrigated lands, much of the habitat occupied by these species is not suitable for crops.

Second, poisoning of prairie dogs as a means of reducing competition with domestic livestock for forage accelerated with agricultural policies in the United States around the time of World War I. Significant Federal funds became available for poisoning programs across the West from approximately 1918 to 1971, after which the use of many of these chemical rodenticides was banned. Tens of millions of hectares of occupied prairie dog habitat were eliminated during this period. Many poisoned prairie dog complexes have never recovered to levels that could support ferret populations.

Third, the exotic disease sylvatic plague, foreign to the evolutionary history of prairie dogs, was inadvertently introduced into North America around 1900. The impact of this disease on prairie dogs and ferrets has been significant. Plague has been documented over all of the ranges of the three principal prairie dog species, except for approximately the eastern third of the black-tailed prairie dog range.

Biologically, the prairie dog ecosystem was devastated by factors described above, and the consequences to ferret populations were even greater. Politically, failure to consider the ramifications of these impacts also resulted in diminished populations of many other species and in several cases led to later consideration of further regulatory protection, such as listings under the ESA. Socially, the domination of farming and ranching activities on most lands in the American West has more severely impacted some species than others. The nadir of occupied prairie dog habitat probably occurred around 1971, when certain toxicants were banned for prairie dog poisoning. Many poisoned prairie dog populations apparently have increased severalfold since that time but remain low relative to historical numbers. Nevertheless, the limited recovery of some prairie dog populations is important in the context of potential ferret recovery and long-range management.

Ferret occurrence undoubtedly mirrored fluctuations in prairie dog populations. Steadily declining numbers of credible ferret sightings occurred during the 1950s and 1960s. The last population of a few dozen animals was thought to have been located in Mellette County, S. Dak., in 1964 (fig. 1). This population was studied through 1974, and a few animals were captured for a captive breeding trial (see below).

Biologically, the initial field studies of wild ferrets in South Dakota provided a starting point for later reintroduction efforts—a small success; however, this population continued to decline in the face of reduced and progressively fragmented habitat. The political will to conserve this individual population through regulatory action did not exist in the era preceding passage of the ESA. This lack of action represented a notable conservation failure inasmuch as, however difficult the challenges of recovering wild populations in native habitat may be, those challenges pale in comparison to the trauma, demands, and resources required for last-ditch captive breeding and reintroduction efforts. Such invasive, intensive recovery programs add many other management dimensions and require more adaptive and risky decisions.

Socially, at the national level, the American public was just becoming aware of the demise of a number of species but had not reacted sufficiently to spur government action to conserve even this last ferret population. At the local level, "business as usual" ranching practices continued to pursue complete eradication of prairie dogs because of their real and perceived competition with domestic livestock. There was little recognition of the ecological importance of prairie dogs and there were no incentive-based initiatives available to conserve this important resource. The lack of understanding and will to maintain viable prairie dog habitats for associated species was a marked failure.

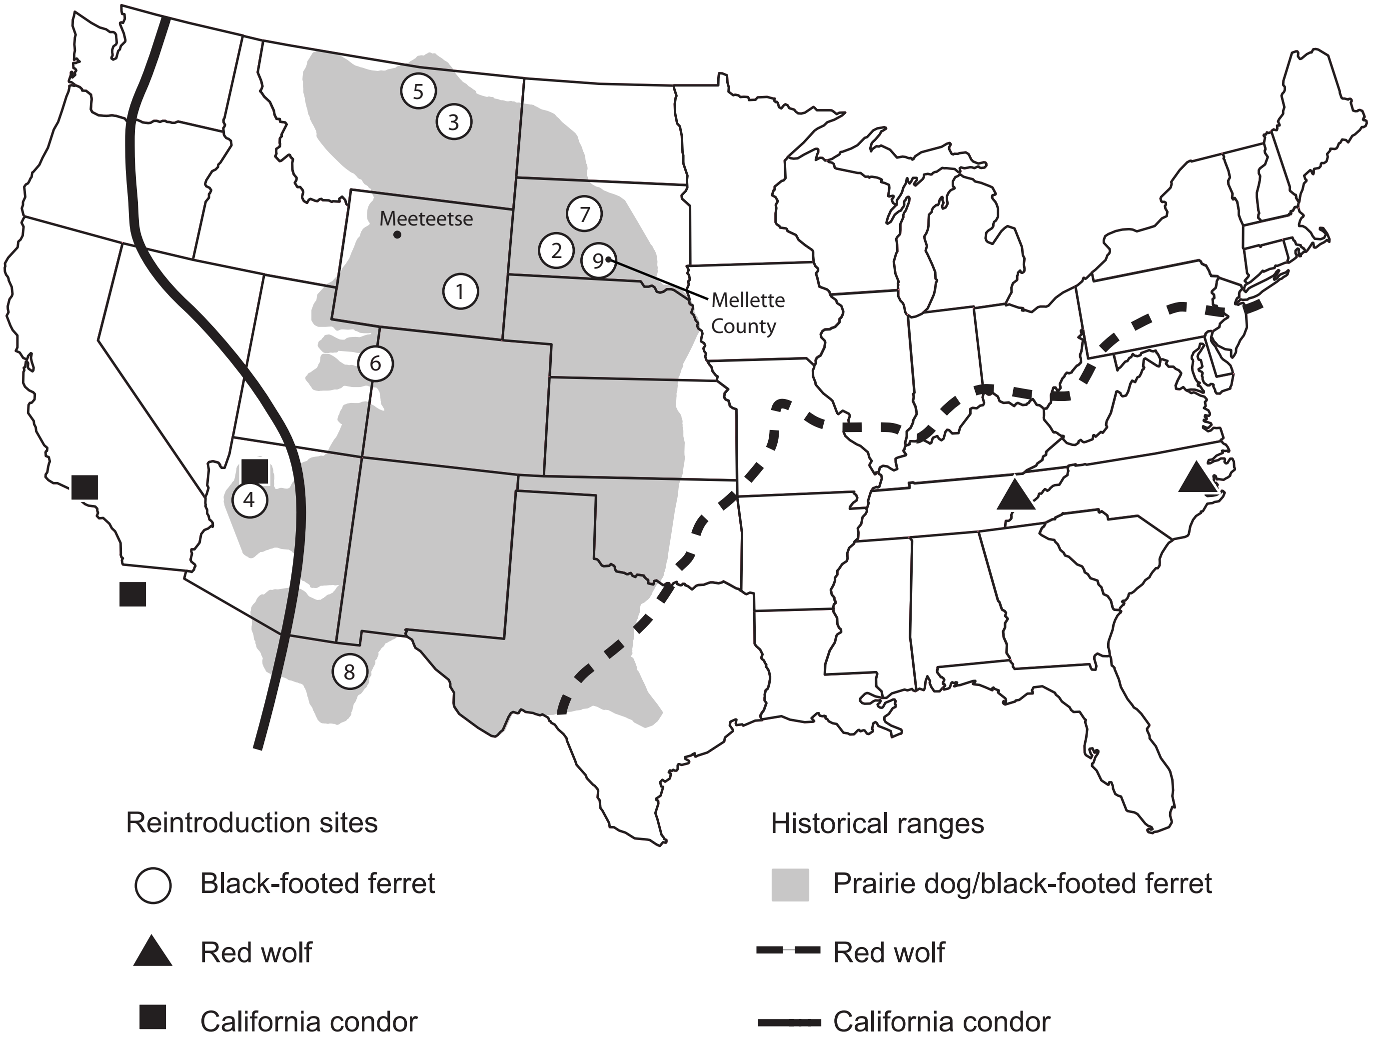

Figure 1. Location of black-footed ferret (*Mustela nigripes*) reintroduction sites overlaid on the collective ranges of three major prairie dog (*Cynomys*) species that are considered their obligate prey. Numbers represent the chronological sequence of ferret reintroductions. Also shown are locations of California condor (*Gymnogyps californianus*) and red wolf (*Canis rufus*) reintroduction sites in relation to their historical ranges.

Are we any more prepared today to deal with such a crisis in a nonregulatory manner? Are means to settle such diametrically opposed concerns readily available if similar circumstances occur again? Unfortunately, we believe the answer to these questions is “no” and reflects another substantial failure in the ability of divergent interest groups, State and Federal agencies, and tribes to find reasonable compromises needed to preserve sensitive species and biological diversity. The inability to find a single ferret in Mellette County, S. Dak., after 1974 was widely regarded at that time as the final demise of the species and must be viewed as a catastrophic conservation failure.

Despite unconfirmed reports, many biologists thought that ferrets were extinct until a ranch dog killed a wild ferret near Meeteetse, Wyo., in 1981. This event ushered in a long recovery process that was widely heralded as a remarkable second chance to conserve a species thought to be lost forever. Intensive attention was focused on this population of over 100 animals (20–40 adults). Considerable field data were acquired from 1981 to 1986 until epidemics of sylvatic plague and canine distemper took a heavy toll on both prairie dogs and ferrets. In hopes of salvaging the species, all remaining wild ferrets were removed from the Meeteetse population between 1985 and 1987 to initiate a captive breeding program.

It must also be acknowledged that underlying social support for endangered species conservation was just beginning to emerge in the 1960s and 1970s. Accordingly, no clear decisionmaking responsibilities were established for ferret recovery during this period, leading to later disputes and second guessing among involved entities. As a means of soliciting advice from experts and interested parties and to help prescribe management direction, WGFD established a Black-footed Ferret Advisory Team (BFAT) in 1982. Considerable acrimony existed within the recovery program during the 1980s and early 1990s, and, although it is never clear when criticism ceases to be constructive, we believe that more assertive and effective leadership by FWS during this period might have helped reduce conflict. We address this issue further in our Summary and Recommendations section.

Despite nearly two decades of extensive and intensive searches, and apart from occasional, unsubstantiated reports, no wild ferrets outside of reintroduction areas have been detected following capture of the last Meeteetse ferret in 1987. Further, we do not believe, given the passage of time and the expansion of plague in western environs, that any undiscovered ferret populations of wild origin exist anywhere in North America today.

With reduced size and quality of prairie dog complexes across most of North America and the presence of plague in many western States, the sustainability of reintroduced ferret populations has also been suspect until very recently. We believe that a wild, self-sustaining ferret population now exists at Conata Basin, S. Dak., and perhaps on Cheyenne River Sioux tribal lands in South Dakota and at Shirley Basin, Wyo. The ability to crop a harvestable surplus of ferret kits from Conata Basin for translocation to other reintroduction areas is a recovery program benchmark of exceptional importance. The Conata Basin ferret population likely represents the largest and most sustainable population that has existed since species listing in 1967, and perhaps for decades before.

Management of wild populations of ferrets (table 1) can be divided into three phases. In comparing these three phases, phase 1, from the mid-1960s to the mid-1970s in Mellette County, S. Dak., ended in disappointment and was greeted largely with resignation. Management efforts during that period were low in intensity and had few available resources. Phase 2, from 1981 to 1987 at Meeteetse, Wyo., was a catastrophe and was largely viewed as a second chance that nearly slipped away. Biological studies at Meeteetse enjoyed considerable resources and were much more intensive, but the existing recovery plan provided little realistic management guidance. Agencies responsible for ferret recovery at that time often disagreed on research and management needs, and required action was sometimes slow to develop. Phase 3, from about the year 2000 and into the future, has a much broader base of support, including a sustainable captive population and multiple reintroduction sites, yet presents new challenges such as habitat improvement needs, genetic management concerns, demographic supplementation in response to adverse stochastic events, diminishing financial resources, and so on. In short, the challenges of continued success now require anticipation of, and responses to, yet unidentified limitations in ferret recovery. Only time will tell whether program collaborators and resources will be adequate to address future uncertainties, but the organizational structure and depth of the recovery program partnership is a successful achievement in its own right and will perhaps ensure more effective responses to any forthcoming environmental or social obstacles.

Captive Breeding

A notable advance in black-footed ferret conservation was the capture in 1971 of six animals from the Mellette County, S. Dak., population for a landmark captive breeding trial. This action was deemed essential because, during the preceding 6 years of field studies in South Dakota, no other black-footed ferret population was discovered nor was any other population known to exist within the ferret's historical range. The 1972 captive breeding attempt was conducted at FWS's (now U.S. Geological Survey's) Patuxent Wildlife Research Center (Patuxent), where management preparations for captive breeding had begun in 1968 with breeding tests of surrogate species (domestic ferrets, *Mustela putorius furo*, and later Siberian polecats, *Mustela eversmannii*). Three additional South Dakota animals were captured and transported to Patuxent for captive breeding in 1972–73.

Efforts to breed black-footed ferrets at Patuxent were crippled from the outset by vaccine-induced canine distemper. Scientists at Patuxent were aware of the susceptibility of domestic ferrets to canine distemper and tested an attenuated distemper vaccine on domestic ferrets to determine safety and efficacy. Although the vaccine was proven safe in domestic ferrets, it induced fatal distemper in four of six vaccinated black-footed ferrets, demonstrating extreme susceptibility to this common viral disease.

Although only nine black-footed ferrets were available for breeding at Patuxent, four of which were lost to vaccine-induced canine distemper, the effort was modestly successful. Two litters of five kits each were born in successive years to a single female. Unfortunately, no kit survived more than a couple of days. The remaining captive ferrets eventually died, and, unfortunately, the breeding research program using surrogate animals was abandoned.

The Patuxent experience demonstrated that black-footed ferrets could be bred in captivity and that captive breeding might be successful if sufficient animals and resources were available. This experience also provided valuable lessons regarding diseases and endangered species recovery. Testing an attenuated vaccine on a surrogate species proved not to be the fail-safe procedure for ensuring vaccine safety for a highly susceptible, highly endangered species. Infectious diseases and their impacts on small populations became obligatory considerations for future recovery of ferrets and other endangered species.

Early ferret recovery efforts at Meeteetse were marred by poor planning, inadequate resources, conflict, controversy, and crisis. Events subsequent to discovery of the Meeteetse population have been, and will continue to be, used as both good and bad examples of endangered species management.

Table 1. Key events in recovery of the black-footed ferret (*Mustela nigripes*).

Year	Wild populations	Captive populations	Reintroduced populations
1964	Small wild population found in South Dakota		
1972		First captive breeding trials at Patuxent Wildlife Research Center, Laurel, Md.	
1974	South Dakota population extirpated		
1979		Last captive from South Dakota dies; species presumed extinct	
1981	Last known free-ranging population discovered near Meeteetse, Wyo.		
1986		First captive breeding effort using Wyoming stock	
1987	Last live ferret removed from Meeteetse; population extirpated	First successful reproduction and weaning in captivity	
1989		First of several additional captive breeding facilities established	
1991			First reintroduction: Shirley Basin, Wyo.
1994			Second and third reintroductions: Conata Basin/Badlands, S. Dak., and southern Phillips County, Mont.
1996			Fourth reintroduction: Aubrey Valley, Ariz.
1997			Fifth reintroduction: Fort Belknap, Mont.
1999		Captive population objective established in Species Survival Plan® reached; captive population considered stable	Sixth reintroduction: Colorado/Utah border
2000	First reintroduced population with harvestable surplus of kits for translocation to other sites		Seventh reintroduction: Cheyenne River Sioux tribal lands, South Dakota
2001			Eighth reintroduction: Janos, Chihuahua, Mexico
2002	Wild ferrets exceed captive ferrets in number		
2003			Ninth reintroduction: Rosebud Sioux tribal lands, South Dakota

Black-footed ferret recovery efforts in the 1980s and early 1990s were highly scrutinized and frequently criticized, often by individuals uninformed about recovery events and/or Federal and State laws regarding endangered species management. Although some reviewers and participants were well-intentioned and constructive, others ignored difficult problems and overlooked lessons learned in earlier ferret recovery efforts and other endangered species programs.

The Black-footed Ferret Recovery Plan of 1978 was written at a time when ferrets were thought to be extinct, and it provided little or no effective guidance for management of the Meeteetse population. In March 1982, WGFD quickly formed the aforementioned BFAT. This multiagency and private sector committee provided advice and guidance to WGFD in determining management direction for the Meeteetse population. Black-footed ferret numbers at Meeteetse increased from discovery in 1981 through 1984, when the population comprised approximately 40 adults and 90 juveniles. Based on this somewhat robust population and because no other wild population had been found (despite increased interest and improved search techniques), WGFD and FWS jointly decided in May 1985 to capture a small number of black-footed ferrets the following fall to begin a modest captive breeding trial. The WGFD's Sybille Wildlife Research and Conservation Education Center (Sybille) near Wheatland, Wyo., was selected as temporary quarters for captured ferrets. Ultimately, knowledge gained from Patuxent was used to develop technology and facilities at Sybille to support a long-term captive breeding program that would eventually provide animals for reintroduction and protect the species from extinction in the event of an unexpected catastrophe at Meeteetse.

The decision to initiate a captive breeding program did not come easily or without conflict. It took optimism generated by the high number of black-footed ferrets documented in the fall of 1984 and assurances that funding would be supplied by FWS in 1986 or 1987 for WGFD to commit to captive breeding. Although captive breeding was started less than 4 years after discovery of the Meeteetse population, in hindsight it should have been started earlier. The delay is understandable, however, and can be largely attributed to uncertainties in the availability of funding and suitable facilities and to the fear of animal loss and breeding failure. Lessons learned through this process were twofold: captive breeding of critically endangered species should be initiated early, and adequate advance planning and committed funding for personnel and facilities are essential. These lessons are not unique to the black-footed ferret program and were applicable to other endangered species, including the red wolf (*Canis rufus*) and California condor (*Gymnogyps californianus*).

The importance of these lessons became evident in the summer of 1985, even before the first attempts to capture ferrets for breeding. In June 1985, sylvatic plague was identified in Meeteetse prairie dog colonies. Sylvatic plague usually causes extensive die-offs in affected prairie dogs. In an attempt to halt the disease episode (by killing flea vectors of plague), FWS and WGFD conducted a massive plague-control program and dusted approximately 80,000 prairie dog burrows with the insecticide carbaryl. Nevertheless, the epizootic reduced Meeteetse prairie dog colonies by about 20 percent in the first year. Although the susceptibility of prairie dogs to sylvatic plague was well known, at that time black-footed ferrets were thought not to be susceptible. Siberian polecats, domestic ferrets, and other mustelids and carnivores are largely immune to sylvatic plague. Several years later, it was discovered that black-footed ferrets are actually exceptionally sensitive to plague. Black-footed ferret numbers at Meeteetse declined sharply over the summer of 1985, and only 58 animals were documented by August.

In September and October 1985, six ferrets were captured for captive breeding trials and moved into temporary quarters at Sybille. These captures led to discovery of another cause of the decline of ferret numbers at Meeteetse. One of the last two animals trapped died from canine distemper, an illness undoubtedly contracted before capture. Based on the experience at Patuxent with vaccine-induced canine distemper and the highly contagious nature of this disease, it was predicted that the remaining black-footed ferrets originally transferred to Sybille would succumb to the disease, which proved true. It was also predicted that most, if not all, animals in the free-ranging population at Meeteetse would be lost. Although extensive precautions had been taken to prevent introduction of diseases from outside sources, no precautions were taken to guard against known ferret diseases within the free-ranging colony. Another lesson learned.

At that point, management of the free-ranging black-footed ferret population and the fledgling captive breeding program were thrown into crisis. Given the reduced numbers of ferrets, it was unlikely that simultaneous efforts to maintain a wild population and start a captive breeding program would succeed; given the presence of disease, it was questionable whether a wild population could realistically be preserved. The WGFD, an agency accustomed to managing free-ranging wildlife, quickly, but with difficulty, decided to begin a second capture effort to obtain founders for captive breeding. This action was taken with recognition that it would likely lead to extirpation of the wild population. Interestingly, opposition to this second capture effort came primarily from individuals who disagreed with human interference and felt that black-footed ferrets should be allowed to go extinct.

In October and November 1985, six more ferrets were captured and placed in strict isolation quarters at the University of Wyoming until it was certain that all were free of canine distemper. Capture efforts were halted in late fall in the hope that any free-ranging black-footed ferrets remaining at Meeteetse would breed in the wild. Also during this period, WGFD invited the Conservation Breeding Specialist Group (CBSG) of the Species Survival Commission of the International Union for the Conservation of Nature and Natural Resources to provide expert advice on developing a captive breeding program.

Captive ferrets did not breed during the 1986 season, probably because of male immaturity and stresses associated with capture and a captive environment. Recovery partners experienced especially difficult times in 1985 and 1986. The responsible agencies received pointed and outspoken criticism; accusations ranged from allegations of mismanagement to intentional exposure of ferrets to canine distemper. Conflicting recommendations were received, including capturing all free-ranging black-footed ferrets immediately, removing captive animals from WGFD's care and terminating its role, curbing all further management intervention in the fate of the wild population, and so on. In spite of stresses, alliances between WGFD, FWS, and other recovery partners began to solidify.

Five free-ranging black-footed ferrets survived the canine distemper epizootic at Meeteetse, and two females subsequently produced litters in the spring of 1986. According to a contingency plan prepared by WGFD with assistance of CBSG and approved by FWS, the WGFD decided in August 1986 to capture all remaining animals. The last of 12 known wild black-footed ferrets was trapped in February 1987, and all captured ferrets were taken to a newly completed captive breeding facility at Sybille. The free-ranging black-footed ferret population at Meeteetse was thus extirpated, and the remaining captive individuals became one of the most endangered mammals in the world, as well as the last hope for the species. Survival and future recovery of the black-footed ferret now depended on development of an effective captive breeding program, which at that time had no proven track record.

Events from October 1981 through early 1987 occurred rapidly and developed in the absence of a current or applicable recovery plan, but critical decisions were still necessary. Perhaps issues faced by WGFD, FWS, BFAT, and CBSG could have been better anticipated and addressed, including analysis and consideration of probabilities of extinction of the small Meeteetse black-footed ferret population; when and how to best initiate captive breeding efforts; how to fund captive breeding; potential responses to epizootics of canine distemper and sylvatic plague; when and how to remove the last free-ranging animals to prevent extinction; appropriate responses to discovery of another wild ferret population; and advance identification and preparation of suitable reintroduction sites.

By spring of 1987, with funding assistance from FWS, the captive black-footed ferret colony was moved into permanent facilities at Sybille. With the assistance of CBSG and the University of Wyoming, WGFD improved captive husbandry protocols, began a genetic management plan, and began intensively monitoring black-footed ferret reproductive cycles and pairing events. Captive breeding techniques were developed with the intent of minimizing stress and injury and maximizing longevity, productivity, and genetic contribution of founder animals without promoting domestication. Two litters were born, and seven kits were weaned in 1987. Production of these kits was exceptionally significant, not because of the number of kits weaned or their genetic makeup but because it was finally demonstrated that black-footed ferrets could be bred and reared successfully in captivity.

The CBSG, WGFD, and FWS held a workshop on black-footed ferret conservation biology in 1986. A captive breeding program plan (*A Strategic Plan for the Management of Black-footed Ferrets in Wyoming*), with time-specific objectives, was written in 1987. This plan recognized that few animals were available for captive breeding and that many were related. It called for maintaining approximately 90 percent of the original genetic heterozygosity of founder ferrets over a relatively short period of 50 years. This would be accomplished by establishing a captive population of 500 animals with a stable age and sex distribution, which would provide an effective population of about 250 ferrets and approximately 200 breeding-age animals. During the early stages of the program, increasing the population had priority over managing genetics. Subsequently, ferret pairings were planned to maximize retention of founder alleles.

Another objective of the strategic plan was to raise enough animals to establish a second geographically removed population to protect the species from catastrophic loss. The two-facility objective was reached in 1988 when a few ferrets were moved from Sybille to the Henry Doorly Zoo, Omaha, Nebr., and the National Zoological Park's Conservation & Research Center, Front Royal, Va. Demographic and genetic data were maintained in a detailed studbook. Separate captive populations were genetically managed and bred as a single population. The strategic plan also called for initial ferret reintroductions to begin in 1991, provided that the captive population reached 500 animals with 200 breeding-age adults.

A revised Black-footed Ferret Recovery Plan was completed by FWS in 1988. It included most of the goals of the Wyoming strategic plan and called for ensuring immediate survival of black-footed ferrets by increasing the captive population to 200 breeding adults by 1991. Additionally, it included a downlisting goal of establishing a prebreeding population of 1,500 free-ranging, breeding-age ferrets in 10 or more populations, as widely distributed as possible over the historical range, by the year 2010.

Over the next few years, additional captive populations were established at the Cheyenne Mountain Zoo, Colorado Springs, Colo.; the Louisville Zoo, Louisville, Ky.; the Metropolitan Toronto Zoo, Toronto, Ontario, Canada; and the Phoenix Zoo, Phoenix, Ariz. The contribution of these zoos to ferret recovery was enormous. They received no monetary support from WGFD or FWS and initially were not allowed to use ferrets for exhibit. Another requirement was that participating zoos be accredited by the American Zoo and Aquarium Association (AZA), which had established a program to develop Species Survival Plans® to facilitate captive breeding of endangered and declining species. With growing involvement of AZA zoos and maturation of the captive breeding program in 1989, the technical advisory role previously filled by CBSG was vested in AZA through an established Black-footed Ferret Species Survival Plan (SSP) and associated Management Group of facility specialists.

The partnership between the AZA's SSP, WGFD, and FWS was, and remains, successful, and black-footed ferret recovery has benefited greatly from this relationship. Participants in the Black-footed Ferret SSP Management Group included representatives from involved zoos, WGFD, and FWS, as well as numerous outside advisors who provided extensive expertise in husbandry, veterinary care, disease, reproductive management, population management, and genetics. The commitment of the SSP Management Group, CBSG, and their many advisors was rewarded in 1991 when captive-bred black-footed ferrets were first reintroduced into the wild at Shirley Basin in central Wyoming.

With expansion of the reintroduction phase of black-footed ferret recovery to sites outside Wyoming, and with dwindling financial resources within WGFD, management responsibility for the Sybille captive breeding facility shifted to FWS in 1996. The breeding facility is now part of the National Black-footed Ferret Conservation Center and has moved to a new site in northern Colorado. The new facility became operational in the fall of 2005.

A review of the Black-footed Ferret Recovery Program, with particular attention to captive breeding elements, was undertaken by AZA in 1995, and a similar analysis and update was accomplished by CBSG in 2003. These critical reviews of the history, progress, and operations of captive breeding projects have been instrumental in evaluating problems and providing important input into the direction and management of captive breeding.

Beginning in 1997, an effort was undertaken to increase overall captive production and kit quality for reintroduction purposes. Ferrets excess to the SSP were used to develop limited field breeding projects in association with reintroduction efforts in Arizona, Colorado, and Montana. A separate field breeding facility (no accompanying reintroduction effort) was constructed near Raton, N. Mex., by the Turner Endangered Species Fund. Although many of the basic SSP husbandry and breeding procedures were employed, these projects were initially designed to test more hands-off breeding strategies in outdoor pens with well-developed prairie dog burrow systems. Breeding success at these facilities has been mixed and has varied substantially between sites. In addition, the expense of operating pen breeding facilities has often been greater than anticipated and, as a consequence, has affected other elements of reintroduction projects. The objective of increasing production and potentially improving the survival of released ferrets, however, remains a guiding principle of the recovery program and has been a recurring recommendation in all formal program reviews. Additional evaluation and refinements of pen breeding capabilities warrant further attention.

Although the black-footed ferret captive breeding program will continue to evolve, it has been a great success: the first animals were captured for captive breeding 4 years after discovery of the Meeteetse population; the program survived the sylvatic plague and canine distemper crisis of 1985 and extirpation of the species in the wild by 1987; and the first experimental reintroduction occurred just 6 years after the first animals were captured to initiate captive breeding. The captive breeding program has produced and weaned over 4,800 ferrets (through 2003) and has supported several reintroduction efforts across the former range of the species. In addition, the program has provided animals for essential disease and vaccine research, for survival enhancement, and for educational exhibit. For the foreseeable future, black-footed ferret recovery hinges on the continued success and management of the captive population by involved agency and zoo partners.

Reintroduction

With increasing success in black-footed ferret captive breeding efforts in the late 1980s, recovery program partners focused greater attention on restoring wild ferret populations. Initial interest was directed at reestablishing a ferret population at the site of their last wild origin near Meeteetse, Wyo., but sylvatic plague substantially reduced overall habitat quality on the Meeteetse prairie dog complex, thus rendering the site unsuitable for ferrets. Today, prairie dog populations in the Meeteetse area are still depressed, which highlights a serious obstacle to ferret recovery. In the absence of effective plague intervention and management capabilities, many affected prairie dog colonies may never regain historical population levels and may never support viable ferret populations. This issue is discussed at greater length below.

The primary goal of the black-footed ferret recovery program is to reestablish a sufficient number of viable, wild ferret populations in order to downlist and recover the species, remove it from ESA protections, and terminate the expensive captive breeding program now necessary to support species survival and recovery efforts. Between 1991 and 2003, 12 discrete reintroduction projects were initiated at nine reintroduction areas in six western States (Arizona, Colorado, Montana, South Dakota, Utah, and Wyoming) and at one site in northern Chihuahua, Mexico (fig. 1). The history and results of these specific reintroduction efforts are addressed elsewhere and will not be detailed here. Instead, we highlight overall direction, research, monitoring efforts, ferret survival, and success in general terms and from our personal views and recommended direction.

As of 2003, over 1,800 ferrets had been reintroduced into the wild. Success of these efforts, in terms of establishing self-sustaining populations, has been mixed and affected most significantly by habitat suitability (which, in turn, is most affected in recent years by the presence of sylvatic plague throughout most of the historical ranges of prairie dog species and ferrets). Only in South Dakota do large, relatively contiguous, and plague-free prairie dog complexes remain, and the greatest reintroduction success to date has been at the Conata Basin site (Buffalo Gap National Grasslands) in south-central South Dakota. Conata Basin experienced exponential growth in the wild ferret population following only 3 years of reintroduction and a total release of 165 captive animals. Ferrets at Conata Basin may have spread through most of the available habitat and are possibly approaching population saturation levels, having produced a relatively consistent 60 to 70 litters annually over the past 3 years. Conata Basin is the only site to have reached a success level that allows translocation of wild-born kits to other reintroduction sites, and kits from Conata Basin have been used to support reintroductions in Colorado and at two other sites in South Dakota. Similar successes are expected at two more recent South Dakota reintroduction sites that also support relatively large, plague-free prairie dog complexes (Cheyenne River Sioux and Rosebud Sioux tribal lands). In contrast, plague has been documented either in or around five of the other reintroduction areas outside of South Dakota.

To date, there have been six reintroduction projects in black-tailed prairie dog habitat (Montana, Mexico, and South Dakota), two in white-tailed prairie dog complexes (central Wyoming and an area straddling the Colorado/Utah border), and one in Gunnison's prairie dog habitat (northwestern Arizona). Differences in prairie dog colony size, density, and life history (e.g., hibernation) exist both between and within species (over the extent of each species' range) and undoubtedly influence site quality and success of ferret reestablishment. For the most part, black-tailed prairie dogs currently occupy definable "towns" of varying size (but historically included enormous colonies), exist at greater densities, and typically do not undergo extended torpor. On the other hand, Gunnison's and white-tailed prairie dogs are more scattered and less dense over areas they occupy and hibernate for extended periods.

Other regional factors such as geography, vegetation, annual precipitation, and drought also affect site suitability and reintroduction potential. Land ownership patterns, land use, access, and vehicle use constraints further affect implementation and monitoring efficacy of reintroduction projects. As a consequence of such dynamics, the recovery program has experienced both outstanding and rapid reintroduction success, as well as projects that have struggled to maintain even minimal populations. Still, no reintroduction project is regarded as a failure, and all have provided vital experience and information to help foster ongoing and future recovery efforts across the ferret's historical range. Moreover, given the severe limitations in available reintroduction sites in North America today, it would be imprudent to give up on any reintroduction area that has the necessary land base and potential for improved habitat conditions and ferret recovery.

Only ferrets considered excess to the captive population have been used to support reintroduction projects. The captive, SSP population is regarded as the essential foundation of the species today. And with the exception of ferret releases in Mexico, all reintroductions have been accomplished under a special provision of the ESA (section 10(j)) that provides for designation of reintroduced populations as "nonessential, experimental." Ferrets released into nonessential, experimental population areas (as established via Federal rulemaking and ESA consultation procedures) are no longer classified or managed as endangered but are given protection and management flexibility similar to that provided for "candidate" species (candidates for listing under ESA but not yet listed). This relaxed management flexibility was necessary to gain the support of State governments and private landowners for releases of an endangered species into areas with fragmented ownership patterns of public and private lands.

The section 10(j) nonessential, experimental provisions facilitated ferret reintroduction trials; it is unlikely that most projects would have been successfully implemented without 10(j) or a similar mechanism to reduce the perceived consequences of potential expansion of endangered ferrets onto private lands. The nonessential, experimental designation has other limitations that impede ferret recovery, however, and a review of the utility of 10(j) and reexamination of other options to tailor reintroductions to site-specific situations are warranted. More discussion is provided below.

With the recovery program becoming more focused on reestablishing wild ferret populations in the early to mid-1990s, other forms of partner acrimony began to surface. Disputes over "soft" versus "hard" release techniques, ferret preconditioning and predator avoidance training, predator control, use of radio telemetry to document survival, how and where to prioritize excess ferrets for release, State versus Federal authorities, and other research issues, some of which first began to surface during the Meeteetse era, seemed to deepen divisions among some participants.

Despite individual and agency conflicts and occasional setbacks, a committed partnership of biologists and administrators set aside differences (or, perhaps more accurately, worked around them) to focus attention on biological and social impediments to ferret recovery. As a consequence, reintroduction efforts continued to gather momentum between 1991 and 2003, and a wealth of information was gathered over that period about how to effectively reestablish ferret populations and respond to obstacles.

Also, the recovery program experienced a somewhat unexpected and positive turnaround in the status of two reintroductions over the past several years. Reintroductions at Shirley Basin, Wyo., were suspended in 1994 because of an extensive plague outbreak. Subsequent monitoring suggested that the small remaining ferret population was likely to be lost by the end of the 1990s; however, starting in 2002, the Shirley Basin population exhibited its own exponential growth and appears to be rapidly developing into a self-sustaining population. Prairie dog populations in Shirley Basin are also rebounding. Likewise, wild ferret production at Aubrey Valley in northwestern Arizona has recently increased following years of reintroduction attempts, probably as a result of spring ferret releases (releases designed to place ferrets in the wild when they can best exploit prairie dogs emerging from hibernation and young pups).

Perhaps one of the most significant findings from the early reintroduction development stages was recognition of the importance of preconditioning captive ferrets prior to release in the wild and an associated partner commitment to expand preconditioning capacity by constructing a number of outdoor facilities at or near reintroduction sites in Arizona, Colorado, Montana, New Mexico, and South Dakota. In simplest terms, preconditioning is the exposure of captive-produced ferrets to a more natural outdoor environment with relatively large pens, prairie dog burrow systems, and live prairie dog prey. In these pens, cage-reared ferrets become accustomed to the security and life needs of prairie dog colonies; essentially, they learn to behave like wild ferrets. As addressed above, outdoor pen facilities in Arizona, Colorado, Montana, and New Mexico were also used to conduct experimental breeding trials to increase the number of animals available for reintroduction.

Certainly, much has been learned about reintroducing ferrets. Still, many pressing uncertainties remain, particularly those dealing with management of ferrets in plague-affected environs, and additional research and reintroduction trials are warranted. And perhaps one of the best ways to speed recovery is to “cast a wide net” by placing ferrets in as many potential sites as possible and letting ferrets ultimately reveal what constitutes favorable habitat and management conditions.

As noted above, in 1995 the AZA was contracted by FWS to conduct a comprehensive review of the ferret recovery program. In this review, the AZA examined the status and success of captive breeding and reintroductions, as well as the administration and general decisionmaking procedures of the program. Much of the information was gathered through a series of partner workshops. A final report to FWS in 1996 included many valuable and specific recommendations on the biological and administrative needs of the recovery program. With waning funding in WGFD and expanding recovery efforts beyond the State of Wyoming, in 1996 FWS assumed primary responsibility for operation of the Sybille breeding facility and management of captive and field recovery activities. Following guidance provided in the AZA report and as set forth in ESA, FWS also established the Black-footed Ferret Recovery Implementation Team (BFFRIT) in 1996 and invited participation of agencies, organizations, and tribes directly involved in ferret recovery activities.

The BFFRIT replaced the original BFAT and subsequent Interstate Coordinating Committee as the vehicle for maintaining partner coordination and input into recovery program direction. The BFFRIT is composed of 26 cooperating State and Federal wildlife and land management agencies, tribes, zoos, conservation organizations, and the National University of Mexico. The BFFRIT charter established the Executive Committee (administrators of agencies/organizations who address recovery program policy and funding issues), the Conservation Subcommittee (composed of technical experts to deal with field reintroduction and research elements), and the Education Outreach Subcommittee (to expand public awareness of the recovery program and help pursue outside funding opportunities). The SSP Management Group, established originally by the AZA in 1991 and made up principally of zoo representatives, also effectively serves as a technical subcommittee to the BFFRIT and provides input and expertise on management of captive breeding programs.

Although FWS retains ultimate authority, the BFFRIT provides essential input and recommendations on all matters related to ferret recovery and has effectively guided program direction since its inception. To establish more balanced and objective procedures for allocating ferrets for reintroduction and research purposes, FWS (through the BFFRIT) also developed an annual ferret allocation and project evaluation process in 1996. This allocation process sets priorities for ferret distribution based on the biological suitability of proposed release sites, overall project and/or research merit, and potential recovery program benefits. Allocation proposals, which provide details on habitat attributes of project areas, disease and predator presence and management capabilities, project/research design and implementation capabilities, and so on, are submitted to FWS by mid-March each year. The proposals are then distributed to BFFRIT members for review.

The FWS awards a preliminary ferret allocation in late May via a report that fully discloses (albeit anonymously) comments and recommendations provided by BFFRIT members and a justification of FWS findings. The number of ferrets identified in the preliminary allocation is determined from an expected production level based on a 5-year average recruitment rate from the number and age distribution of female ferrets presently in the SSP-managed population. For now, and into the foreseeable future, first priority for ferrets goes to SSP facilities to maintain the genetic representation and viability of the essential captive population. Final allocation decisions are made in late summer and depend on the actual production achieved by SSP facilities and field breeding projects, as well as on resolution of any permitting or other project implementation deficiencies (e.g., funding, partnership commitments).

The current organizational structure of the Black-footed Ferret Recovery Program has had the benefit of time, conflict, and critical analysis to evolve. Fortunately, ferrets have persisted during periods of unforeseen crises and human mistakes. The BFFRIT is a product of important lessons learned over the history of the ferret program, and we believe it offers a good example of an effective strategy for management of large, complex, endangered species recovery programs. Instead of a typical, more academically based and smaller recovery team, a recovery implementation team provides a transparent decision process and equal voice to a large number of involved agencies, tribes, and organizations. Although FWS retains ultimate authority and responsibilities as specified in the ESA, the BFFRIT is relied on to help make informed program decisions, help resolve partner disagreements and other program conflicts, and generally keep recovery efforts moving in a positive direction. We regard such continued partner participation as essential to successful recovery of the black-footed ferret.

Finally, the most pressing limitation to ferret recovery is availability of suitable habitat to restore and support wild populations. Although program partners have always understood that habitat availability is key to recovery, other program imperatives between 1985 and 1997 (i.e., development of captive breeding and reintroduction capabilities) somewhat diluted focus on habitat issues. In 1998, the BFFRIT Conservation Subcommittee was tasked to identify and prioritize the top 10 sites that could support ferret reintroduction across North America, as well as secondary areas that could possibly be developed into additional reintroduction sites. In 1988, only 10 years earlier, an internal FWS document suggested that as many as 38 suitable ferret reintroduction areas existed in the United States. That document was based solely on suggestions from program partners and did not attempt to accurately assess current prairie dog populations, complex size and quality, the status of plague, or other practical biological and political factors (e.g., land ownership patterns) necessary to determine reintroduction potential.

With more detailed surveys of BFFRIT partners, the 1998 assessment of site potential indicated that only nine sites could immediately support ferret reintroductions across North America. Five of these sites were already engaged in reintroduction projects, and three more were activated between 1998 and 2003. Since 1998, a few other potential release areas have been identified, but it is clear that prairie dog habitat throughout the historical range of the ferret has been so severely degraded that ferret recovery is not feasible without restoration of large, healthy prairie dog complexes.

What constitutes a suitable prairie dog complex for ferrets is a question still under scrutiny by program partners and is a pertinent issue to be addressed in an upcoming and long overdue revision of the Black-footed Ferret Recovery Plan. In examining the results of reintroduction efforts to date, the only relatively large, self-sustaining, wild population of ferrets (ca. 250–400 animals) is at Conata Basin, a site that contains some 6,070 ha of closely distributed and relatively dense black-tailed prairie dog colonies—prairie dog colonies that are also free of sylvatic plague and are managed to preserve high prairie dog habitat values. Although prairie dogs of all three species are well dispersed throughout their former ranges, prairie dog complexes are very small and highly fragmented compared to historical conditions. There are very few places within North America that approximate the quality of habitat for ferret recovery exhibited at Conata Basin.

The revised Black-footed Ferret Recovery Plan (published by FWS in 1988) sets forth a downlisting objective by the year 2010 of 1,500 adult (breeding) ferrets, established in no less than 10 separate populations across the historical range of the ferret, with at least 30 individuals in each population. Although a prebreeding census of 1,500 adult ferrets may be attainable with continued recovery success in the few large prairie dog complexes that exist, there appear to be only four or five sites today that have the potential to support viable ferret populations, the majority of which will likely be in plague-free complexes in South Dakota.

Future recovery of the black-footed ferret hinges on our ability to successfully reintroduce and reestablish relatively large, healthy populations in the wild. Unlike two other endangered, high-profile carnivores of the West, the gray wolf (*Canis lupus*) and grizzly bear (*Ursus arctos*), the entire breadth of habitat within the ferret's historical range has been materially impacted: there are few large expanses of Federal public land with sufficient prairie dog habitat to support black-footed ferret populations at the present time. Furthermore, although the amount of land potentially available for habitat restoration across the historical range of the ferret far exceeds potential capabilities for two other critically endangered species, the California condor and red wolf (fig. 1), there are significant social and political impediments to restoring and managing large blocks of grasslands for prairie dogs and ferrets. Prairie dogs are still largely regarded as vermin by private landowners and agricultural interests, and only small, relatively fragmented complexes are typically tolerated, if at all.

And so, ironically, we appear to be at yet another important crossroad for this species. Having brought the ferret back from the brink of extinction, having invested enormous national resources to right an ecological wrong, and having developed the necessary capabilities and expertise to actually recover this species, the future of the ferret hangs on our social and political will to set aside and develop sufficient habitats that could be managed for prairie dogs, ferrets, and other sensitive prairie wildlife species. Ferret recovery efforts have come full circle, and it will be an enormous challenge to overcome a prevailing attitude of “not in my backyard” when so few suitable, welcoming backyards are presently available.

Summary and Recommendations

Given the status of the ferret in 1987, when only 18 live animals remained, we submit that ferret recovery has been one of the most successful endangered species programs to occur anywhere, at any time. Table 2 compares several recovery parameters for three well-known North American species that were listed as endangered in 1967. The black-footed ferret, California condor, and red wolf are notable “grandfathered species” that have always been included in the various versions of ESA. Each became further imperiled after listing, and each was subsequently removed from the wild for captive breeding and eventual reintroduction. Figure 1 indicates the historical range of these species and the sites where reintroduction has occurred. Clearly, the “recovery glass” is potentially “half full” for the ferret compared to species that mature less quickly, have fewer young, and whose range and essential habitats have been even more drastically altered.

The lessons taught by ferrets, condors, and red wolves should be carefully heeded. Reducing any species to such critically low population levels that captive breeding becomes the only possible recovery strategy is a poor way to ensure persistence, much less recovery. Extinction risks are elevated, recovery becomes more expensive, and bringing species into captivity may remove assurances that adequate habitats will be available for later reintroduction.

Table 2. Comparisons of some recovery parameters for three North American endangered species removed from the wild, propagated in captivity, and reintroduced into their historical ranges, 1967–2003.

	Black-footed ferret (*Mustela nigripes*)	**California condor (*Gymnogyps californianus*)**	**Red wolf (*Canis lupus*)**
Year species listed	1967	1967	1967
Year extinct in wild	1987	1987	1980
Number removed from wild	18	27	17
Initial number used in breeding	7	14	14
Number propagated in captivity to date	4,800+	283	727
Number held in captivity, breeding	~400	130	300
Year reintroduction began	1991	1992	1987
Number reintroduced to date	~1,800	~167	~120
Number of attempted reintroduction sites	9	7	2
Number weaned or fledged in wild	~1,200	1	289
Number in wild	~600	~80	~100
Reintroduction sites, likely viable	3	0	1
Reintroduction sites, not viable	2	0	1
Reintroduction sites, unknown viability	4	7	0

The ferret recovery program has experienced a number of successes, failures, and hard-learned lessons over the years. It is important to continually characterize progress so the direction and speed of recovery can be adjusted accordingly. Overall, we believe that the ferret recovery program will probably continue to be successful, despite many near disasters and remaining obstacles. Ferret recovery efforts may be compared internally by contrasting results of different activities over time. Comparisons of the progress and success of other endangered species recovery efforts may also provide perspective that will aid ferret recovery.

To date, we believe that (1) black-footed ferret captive breeding has been highly successful, (2) ferret reintroductions have achieved a low to moderate degree of success, and (3) wild population management has experienced a low degree of success. Marked improvements and efficiencies have occurred in all of these areas over the last decade, however.

The most notable success of captive breeding has been the creation of a mutually supportive network of staff and facilities that successfully raise animals in a protected environment to ensure species survival and provide animals for reestablishment of wild populations. Problems that have occurred in this recovery component have been straightforwardly addressed. One nagging limitation that may or may not be possible to fully overcome in a captive environment is the relatively low whelping success in females (as compared with wild whelping rates). The most important lesson learned over the course of the ferret program, however, is that biological breakthroughs in complex recovery efforts can only be realized via the successful involvement of many diverse partners.

Ferret captive breeding may become more efficient as limitations are identified and addressed, but this recovery component is mature, with over 15 years of accumulated experience. Most attainable internal refinements may already have been achieved. If increased numbers of animals are required for reintroduction, it may be most practical simply to increase the number or size of facilities. Captive breeding of ferrets is a tightly controlled process with few extraneous factors affecting its continued success or failure. Extended captivity may reveal future biological constraints (e.g., inbreeding suppression), but most political and social obstacles to captive breeding appear to have been adequately addressed.

At present, the knowledge and resources needed for continued success of the captive breeding program appear to be in place. Nevertheless, we recommend that continued and rededicated attention to partner coordination and involvement be nurtured through the SSP Management Group and BFFRIT. Although this recommendation may appear gratuitous given present successes, renewed emphasis is essential to address a crucial, laborious, and continuing program element whose failure would undercut all other recovery activities. A recurring error of many recovery efforts is to gradually pay less attention to successful foundation components when new limiting factors are identified.

Likewise, progress in reintroducing ferrets and establishing viable, wild populations requires continued nurturing of program cooperators and development of new partnerships with other States across the ferret's historical range. The most notable success of the reintroduction component has been the relatively rapid involvement of the few suitable sites for active releases, but few large, high-quality prairie dog complexes remain, and future recovery depends on both short-term and long-term habitat restoration. In concert with renewed efforts to identify and enhance potential recovery habitat, new reintroduction trials and continuing research to refine vaccines and develop other possible disease management capabilities are also essential.

The most notable accomplishment of wild population management has been the apparent sustainability of at least one reintroduced population. The ferret population at Conata Basin, S. Dak., is believed resilient enough to withstand harvest of surplus animals for translocation to other reintroduction sites. This is a remarkable accomplishment and indicates a population likely more stable than any other extant population during the last half century.

The review of the Black-footed Ferret Recovery Program by CBSG in June 2003 and the subsequent report issued by CBSG in January 2004 provided many practical recommendations to further ferret recovery and addressed issues and program needs related to captive breeding, reintroduction, disease, and habitat. Many of our views and recommendations echo information contained in the CBSG report; however, given the current status of the recovery program, after almost 20 years of captive "life support" for the ferret, and the prospect of a difficult recovery future (given habitat limitations), perhaps other, more fundamental questions need to be asked and other key recovery priorities more fully pursued.

To realistically fulfill our recovery mission, how do we secure greater commitments for financial resources, private land incentives, and public land-use reforms necessary to set aside, develop, and sustain sufficient habitats across the historical range of the ferret?

Given the presence of plague in the environment and the timetable likely necessary to restore suitable prairie dog complexes, a foundation of available sites needs to be identified and attendant implementation strategies and schedules prescribed in a timely manner. It may take 10–20 years of intensive management to enhance complexes of prairie dog habitat to the point that they can support healthy ferret populations; planning and commitments must start soon. Federal public lands (national grasslands, Bureau of Land Management property, national wildlife refuges, national parks and monuments, and military lands) should bear a disproportionate amount of habitat development. Responsibilities under section 7(a)(1) of the ESA (a provision requiring all Federal agencies to fully promote and support endangered species recovery) should be reinforced at the national level, both with funding and refocused priority, to establish and manage large prairie dog complexes wherever possible. Partnerships with tribes and private land owners must be pursued to secure recovery areas over those portions of the ferret's historical range where public lands are largely absent. Cooperative efforts with Canada and Mexico should continue in order to develop recovery sites at the northern and southern extents of the ferret's historical range.

How can administrative procedures be improved to more effectively and rapidly develop suitable black-footed ferret reintroduction areas and secure long-range management assurances necessary to perpetuate viable, wild populations?

All ferret reintroductions in the United States have been accomplished under ESA section 10(j) provisions, which relax many of the strict prohibitions of the ESA. Section 10(j) has been an important management tool and was necessary for initial ferret reintroduction efforts. Nevertheless, 10(j) also has limitations and liabilities. Despite successful development of ferret reintroduction projects over most of the best remaining habitats in the United States since 1991, the administrative processes required to establish 10(j) experimental population sites typically require 2 years to complete and considerable investments of staff and funding. It is not a provision that allows rapid response to new opportunities. More importantly, 10(j) is somewhat one-sided in effect and does not provide long-range assurances of support by affected parties. It can hinder implementation of program changes in response to identified needs and has been used by involved agencies to justify positions of social and political expediency rather than to fulfill conservation obligations. Other than reducing political opposition to initial reintroduction efforts, 10(j) has done little to assure reestablishment of ferrets.

Still, we do not advocate stronger regulations or constraints to guide ferret recovery; indeed, we suggest the opposite. The time to be most careful and restrictive with species like the ferret, condor, and red wolf is when they are declining, so as to keep them from slipping into such a precarious abyss in the first place. A process is needed through which responsible agencies are given sufficient resources and broader latitude to quickly develop site-specific strategies that define the boundaries of proposed recovery areas, prescribe the scope of agreements, and, like 10(j), hold no private parties accountable for uses or development of their property that might result in inadvertent losses of endangered ferrets. The ferret program needs to become even more proactive and not shy away from potential risks of individual project failure and animal losses. Again, we need to cast a wide net while reducing the fear of repercussions and impacts to private property that accompany efforts to recover endangered species.

How can resources allocated to endangered species recovery at the national level be better prioritized and distributed to address biological imperatives?

The manner in which endangered species program priorities are established and funded warrants review. Although we certainly support other programs and efforts to recover endangered species, overall national priorities should be biologically based and focused on those species in greatest peril and for which habitat protection would have the greatest overall ecological benefit. Black-footed ferret recovery has achieved some remarkable successes despite a history of inadequate funding. Increased funding could have substantially accelerated species recovery, focused greater attention on critical program elements such as habitat conservation and restoration and expanded partnerships, and perhaps would have helped avoid some of the pitfalls encountered.

Enormous resources have been poured into recovery efforts for the gray wolf and grizzly bear in the Rocky Mountain region with great success and public benefits, but these species enjoy stable habitats over significant portions of their historical ranges—habitats that support large, nonthreatened populations to the north. The black-footed ferret has no comparable safety net of extant population reservoirs. Moreover, the grassland/steppe ecosystem upon which the ferret depends is imminently more threatened, and its loss would have far-reaching consequences to a host of other native plant and wildlife species.

We recognize that these questions and suggestions address larger issues of regulation, policy, and current management direction and practices for numerous State and Federal agencies. We also understand that there are no easy fixes and that change may be slow in coming. Still, what better example of a species recovery program could be used as a springboard to critically review functional elements of ESA, interagency coordination and management needs, partnership capabilities, and administrative processes needed to secure greater habitat stability and foster species recovery? These questions and issues are in need of more focused scrutiny and attention by FWS, partner agencies, organizations, and tribes of the BFFRIT and other endangered species programs.

Acknowledgments

General data on red wolf and California condor used in this paper were obtained from FWS recovery program staff. The interpretation and analyses of those data presented here are our own.

Recovery Plans and Recovery Program Analysis Reports

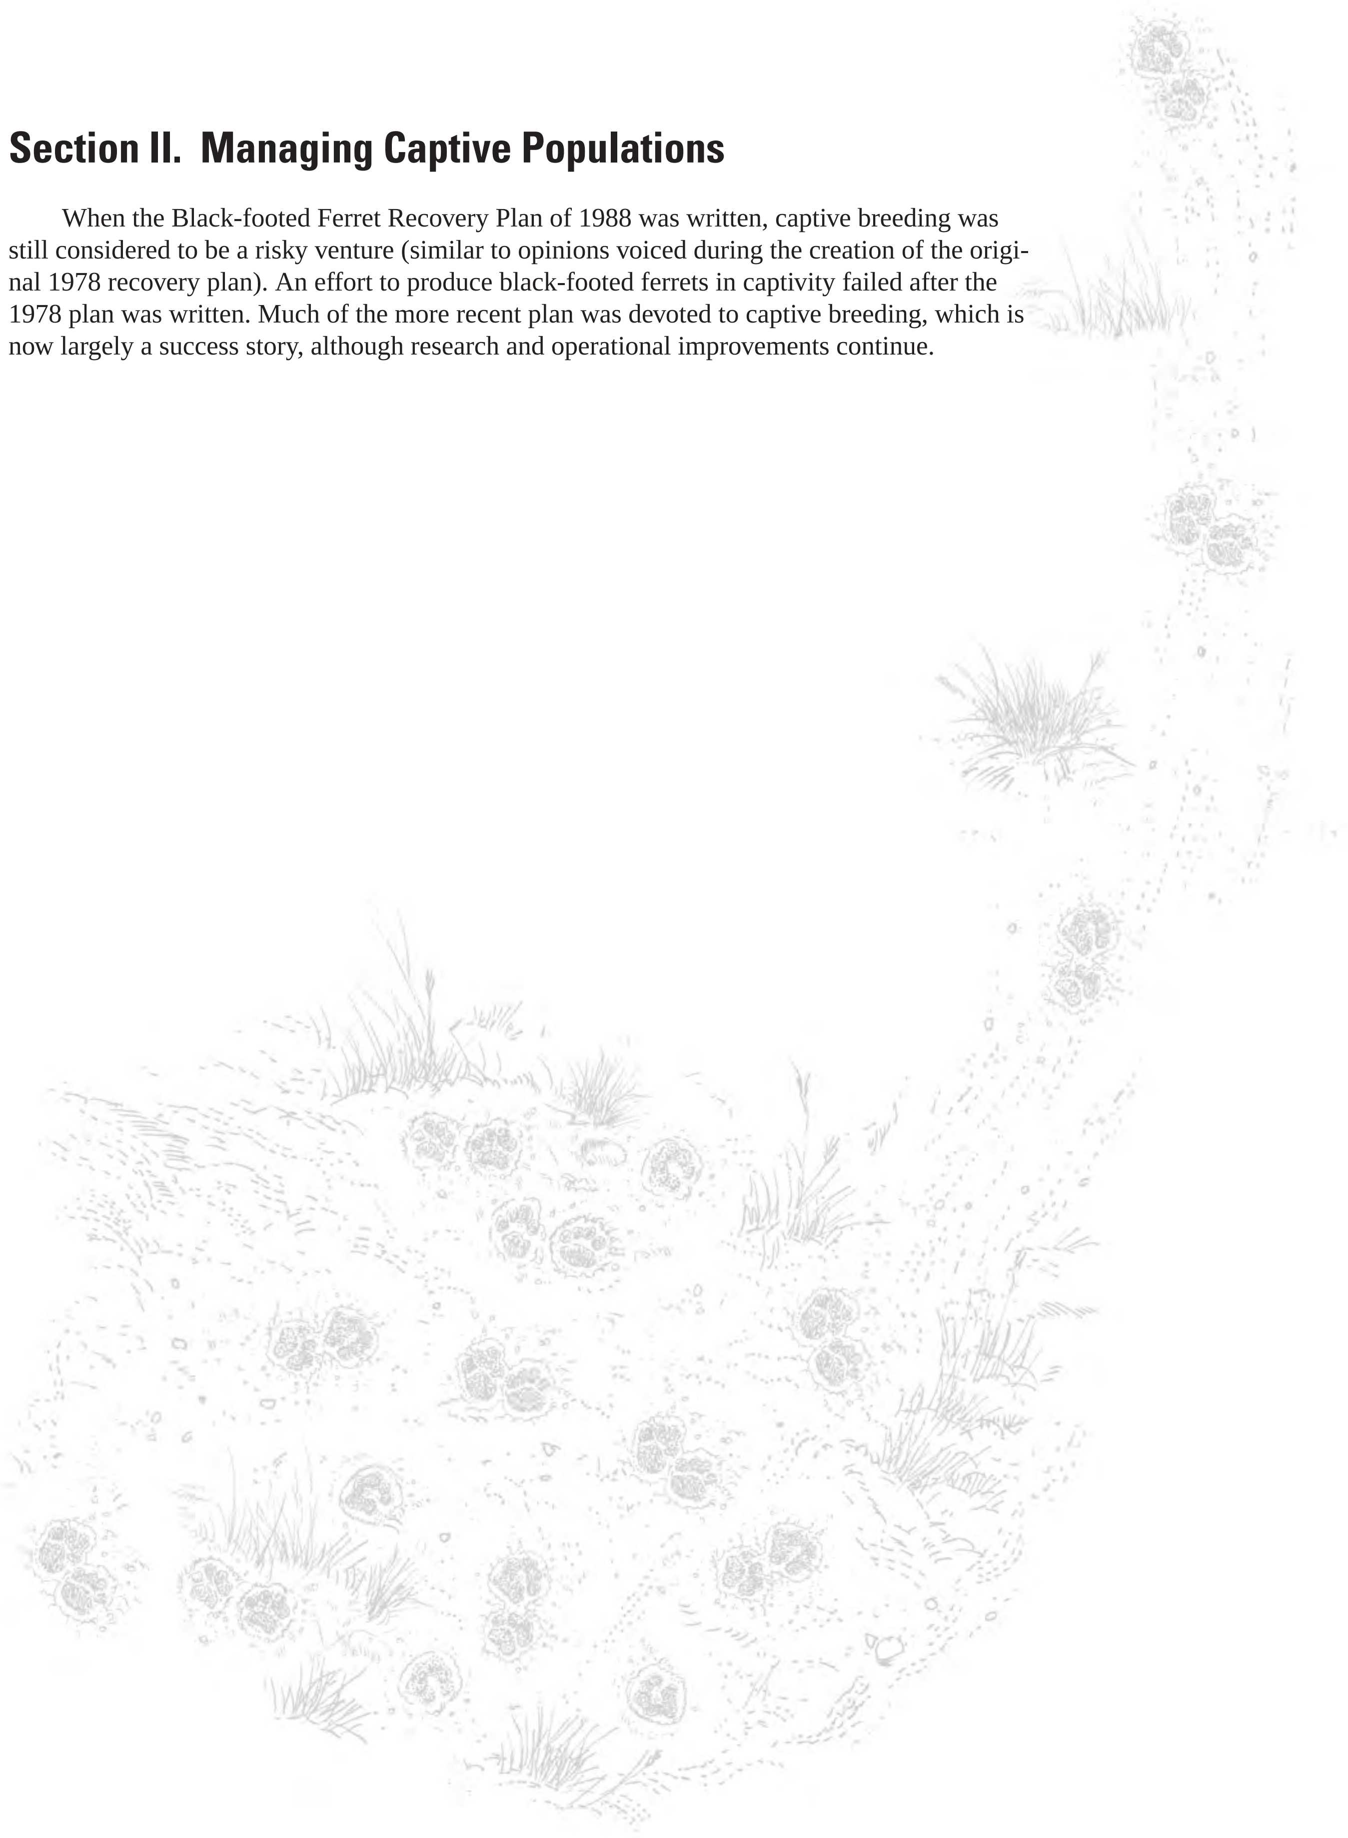
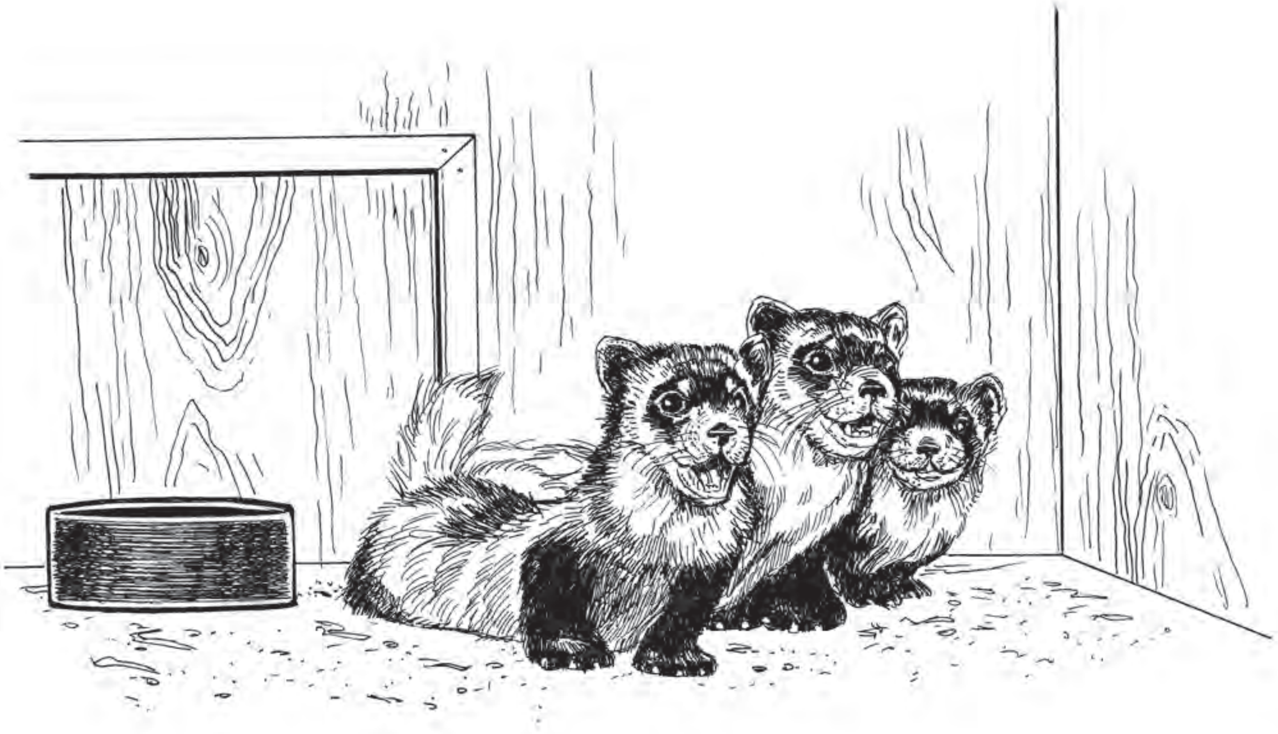
Section II. Managing Captive Populations

When the Black-footed Ferret Recovery Plan of 1988 was written, captive breeding was still considered to be a risky venture (similar to opinions voiced during the creation of the original 1978 recovery plan). An effort to produce black-footed ferrets in captivity failed after the 1978 plan was written. Much of the more recent plan was devoted to captive breeding, which is now largely a success story, although research and operational improvements continue.





An Adaptive Management Approach for Black-footed Ferrets in Captivity

By Paul E. Marinari[1] and Julie S. Kreeger[1]

Abstract

Management of black-footed ferrets (*Mustela nigripes*) in captivity has historically utilized a flexible, adaptive approach as additional information about the species is obtained. Increased survivorship at reintroduction sites within the ferret's historical range has further allowed innovative approaches to animal husbandry. Ferret recovery has benefited from changes in breeding schemes, nutrition, and vaccinations. Production of kits increased when animals were paired during daytime hours and allowed to remain together for 3 consecutive days. The Toronto Zoo Small Carnivore Diet was found to be a well-balanced, cost-effective, nutritious food for ferret maintenance and reproduction. PureVax® Ferret Distemper Vaccine provided protective titers under a variety of management scenarios. Changing program needs and flexibility in animal management are assessed yearly in order to balance maintenance of genetic diversity with maximum productivity.

Keywords: adaptive management, black-footed ferret, breeding, captive, *Mustela nigripes*, nutrition, reproduction, vaccination

Introduction

Captive management of endangered species requires an adaptive approach, incorporating new information relevant to changing program goals while ensuring quality animal care. Additionally, a system of checks and balances is needed to ensure that changes in management do not adversely affect either animal health or the primary goals of captive breeding—productivity and maintenance of genetic diversity. The fate of the black-footed ferret (*Mustela nigripes*) was placed in the hands of captive breeding efforts in the late 1980s when a decline of the last known wild population was identified. The decline of this population, located near Meeteetse, Wyo., led to the capture of 18 individuals of the species and was the start of a complex, multipartner recovery effort, which is conducted under the auspices of the American Zoo and Aquarium Association's Species Survival Plan® (SSP) program and is guided by the Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988) and a manual of husbandry techniques (Lyster and others, 2002).

One of the primary goals identified in the Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988) involves development and maintenance of a large, stable, and genetically managed captive breeding population, which has been further defined as a core breeding population of 240 adults (90 males, 150 females) located in six geographically separated facilities. Facilities currently housing captive breeding populations include the U.S. Fish and Wildlife Service's (FWS) National Black-footed Ferret Conservation Center (Center) in Wellington, Colo., (originally managed by the Wyoming Game and Fish Department and later the FWS at Wheatland, Wyo.), the Smithsonian National Zoological Park's Conservation & Research Center (Virginia), the Louisville Zoo (Kentucky), the Cheyenne Mountain Zoo (Colorado), the Toronto Zoo (Ontario, Canada), and the Phoenix Zoo (Arizona).

At the outset of the captive breeding program, all facilities tried to follow identical animal husbandry and management protocols based on the initial success of the Wyoming Game and Fish Department's (WGFD) program. Since 1987, this has led to the production of over 5,100 black-footed ferret kits through natural breeding and assisted reproductive technology. During this time, much has been learned about ferret behavior, reproductive technology, nutrition, and other factors associated with animal husbandry and captive colony maintenance. The ability to experiment with different management schemes in the ferret program has been key to these achievements. In the mid-1990s, the FWS assumed operational oversight of the largest ferret colony, which is located at the Center. The Center houses approximately 55 percent of the world's captive black-footed ferrets and serves as the hub for all ferret-related activities. Given the large population of ferrets housed there, the Center is an ideal place to implement a flexible and adaptive approach in all areas of black-footed ferret captive management. Additionally, the Center staff works both independently and in collaboration with research-

ers to investigate questions concerning reproduction, nutrition, disease, and genetics as they relate to captive breeding.

Many changes have been incorporated into the captive breeding program based on studies addressing factors that affect the number of kits produced and weaned (defined as kits surviving to 90 days of age). This paper reviews three areas of management that have been addressed through studies at the Center: breeding strategies, nutrition, and vaccination against disease.

Breeding Strategies

A primary goal of the SSP is to optimize genetic management of the captive population (Ballou, 1984; Russell and others, 1994; Miller and others, 1996) by maintaining 80 percent of the genetic diversity present in the founder population for the next 25 years. Since only 7 of the original 18 animals successfully reproduced, genetic diversity has been limited from the outset. Males and females are paired utilizing the mean kinship and inbreeding coefficient strategy (Ballou and Oakleaf, 1989). This strategy identifies several potential males for each female in the SSP breeding population. Efforts to equalize founder representation are succeeding (Wisely, 2001), indicating that the mean kinship and inbreeding coefficient strategy is an appropriate tool for managing the captive population.

Prior to 1996, all ferrets at the Center, as well as those at other captive breeding facilities, were paired by using procedures developed by the WGFD. This involved pairing of animals at night with a high degree of human intervention. Staff at the Louisville Zoo tried a different, less intensive approach to male and female pairings that resulted in very successful kit production. In 1996, Center staff decided to conduct a more extensive study comparing the Wyoming and Louisville methods.

In 1996, the entire ferret colony at the Center was kept under strict quarantine procedures during the breeding season. Access to the animals was limited to immediate staff. Additionally, before coming in contact with any ferrets, all employees showered and changed into clothes that remained onsite. Vehicle traffic near the main breeding building was restricted to emergency use in order to minimize possible disturbance to the ferrets.

Black-footed ferret females were divided between the two breeding schemes being investigated (*n* = 36, Wyoming; *n* = 29, Louisville). Only females aged 1–3 years were included in the study, as these age classes form the core of the captive breeding population. All females were housed in the main breeding building and were treated similarly up to the moment of pairing with their chosen male. Each animal was maintained on a strict diet, known as 60/40, which consisted of a mixture of ground rabbit, commercial mink chow, and various additives, formulated by staff of the WGFD prior to 1996. During the breeding season, rendered lard was added to the 60/40 diet of expectant females only. Two months prior to the breeding season, each ferret was weighed and assigned a target weight that was determined by technicians using visual cues of overall body condition. Amount of food provided to the animals was altered based on weight over a 2-month period. As the breeding season progressed, weekly vulvar measurements were performed and recorded. Vaginal cytology and vulva size were used to monitor reproductive readiness in both groups (Williams and others, 1992). In the Louisville method, males were brought to the females' cages and were not given access to the upper nest box at night. Additionally, once a positive sperm check was obtained, the pair was left together for 3 consecutive days and nights. In the Wyoming method, females were brought to the males' cages, confined to the cage surface (1.2 × 1.2 m), which contained a breeding box, and separated from the males during daylight hours.

Peterson (1996) summarized findings of this study for the FWS's 1996 annual progress report. Fecundity, defined as the proportion of bred females that whelped, was higher with the Louisville method (55 percent versus 36 percent). The average litter size per female bred with the Louisville method was 2.65 ± 2.31 (mean ± SE), which was significantly different from the average litter size for the Wyoming breeding method (1.46 ± 1.82; one-way ANOVA, $P = 0.05$). The average number of kits weaned per whelping female with the Louisville method was 3.13 ± 1.93, which was significantly different from results of the Wyoming method (1.54 ± 1.56; one-way ANOVA, $P = 0.02$).

The higher whelping rate and greater number of kits produced with the Louisville method indicated that this management scheme would be beneficial to overall program goals—maintenance of genetic diversity and production of as many kits as possible. Greater kit production with the Louisville method could be a result of several factors, including less stress because of minimal human interactions while males and females were paired and more time for the animals to copulate, as black-footed ferrets are induced ovulators. Pairs were observed copulating multiple times throughout the day, perhaps providing greater stimuli for ovulation to occur. There is also a cost savings associated with the Louisville method, as additional staff are no longer necessary to monitor pairs at night. Daytime ferret keepers balance activities related to ferret breeding with husbandry chores. The Louisville method has now become standard operating procedure at all captive breeding institutions. At the Center, further refinements have occurred during the past several years to make pairings more efficient. Testicular and vulvar measurements have been discontinued in favor of electroejaculation and vaginal cytology to determine male and female reproductive readiness. Video monitoring has also been discontinued. Sperm checks are now performed opportunistically, and staining (Dip Quick; Jorgensen Laboratories, Inc., Loveland, Colo.) is used to determine the success of pairings.

Nutrition

Black-footed ferrets rely predominantly on prairie dogs (*Cynomys* spp.) for food in the wild (Campbell, 1987). Logistically, it would be extremely difficult to feed all ferrets maintained in the captive breeding program a diet of 100 percent prairie dogs, so alternative diets have been investigated. Initially, captive ferrets were fed a mink chow and rabbit-based diet (the aforementioned 60/40 diet) that included a variety of additives thought to be important for maintaining a healthy breeding population based on information from domestic ferret (*Mustela putorius furo*) and mink (*M. vison*) captive breeding programs. As additional captive breeding facilities were incorporated into the program, feeding strategy guidelines and protocols were relaxed. Several nutritionists were concerned that the 60/40 diet had excessive polyunsaturated fatty acids. Oyarzun and others (1994) analyzed and evaluated common diets used throughout the captive breeding program in the mid-1990s and determined that the 60/40 diet used at the Metro Toronto Zoo (now the Toronto Zoo) greatly exceeded dietary recommendations established for mink as well as nutrient levels reported in the natural diet of black-footed ferrets (Dierenfeld and McGuire, 1989). Oyarzun and others (1994) stated that, even though mineral levels were not high enough to cause acute toxicosis, feeding of higher than recommended levels over an extended period of time might have adverse effects (Lyster and others, 2002). Nutritionists at the Toronto Zoo continued to alter the diet composition so that it more closely fit accepted dietary requirements. This research led to formulation of the horse-based Toronto Zoo Small Carnivore Diet produced by Milliken Meat Products, Ltd., Scarborough, Ontario, Canada.

In 2000, a study was conducted at the Center to compare the two diets (60/40 and Toronto Zoo Small Carnivore) used in the captive breeding program. The primary objective of the study was to examine the effect of the diets on reproductive output. As sample sizes were small (four females and four males in each group), we were looking only for obvious and detrimental deviations from results achieved with the standard 60/40 diet. Larger sample sizes would have provided greater statistical power; however, using additional females in the study might also have reduced our ability to maintain genetic diversity and produce kits for reintroduction. Supplemental vitamin K, believed to decrease the frequency of intra-abdominal hemorrhage (blue-belly) in kits, was provided to bred and nursing females at the same dose and time period for both groups. A less labor-intensive strategy to raise kits was used on all litters at the Center. This strategy not only reduced handling time but also decreased the amount of supplemental diet offered to individual kits. Weights of adults were only monitored during preliminary stages of the study to determine adequate serving sizes and guard against large fluctuations in weight. For females, the number of kits born and those surviving to 50 days of age were examined. Fifty days of age was chosen as a cutoff point for the study because all kits are fed identical diets beginning at that age. The response variable for males was number of sperm per milliliter in ejaculate.

A key advantage to the Toronto Zoo Small Carnivore Diet is that it is made under strict quality control (Canadian Food Inspection Agency). The prepackaged diet was found to be very convenient to use, less labor intensive, and more sanitary than the 60/40 diet produced in-house. The majority of ferrets readily accepted the diet and seemed to prefer it at first feeding. Overall, there was no difference between the two diets in the number of kits born per female (3.5) or the number of kits per female surviving to 50 days of age (3.25). Sperm production appeared to be lower in males fed the Toronto Zoo Small Carnivore Diet, but concentrations were above acceptable limits (250×10^6 sperm/mL). Staff at the Center also noticed that kits readily ate the Toronto Zoo Small Carnivore Diet at early stages of development.

Based on these feeding trials in 2000, the Toronto Zoo Small Carnivore Diet was determined to be effective and convenient for use at the Center and replaced the 60/40 diet; however, in 2003 the United States banned import of all meat products from Canada as a result of mad cow disease (bovine spongiform encephalopathy). Accordingly, we investigated alternative diets, including the Dallas Crown Carnivore Diet (Dallas Crown, Inc., Kaufman, Tex.). Earlier feeding trials at the Phoenix Zoo found this diet to be suitable for ferret maintenance and production. The SSP Nutrition Advisory Group also endorsed the diet as an acceptable alternative if the Toronto Zoo Small Carnivore Diet was unavailable. In keeping with our efforts to improve management in the captive breeding program, in 2004 we also evaluated the effect of the Toronto and Dallas Crown diets on sperm production and compared the results to those from black-footed ferrets fed a more natural diet of prairie dogs. There were no significant differences in the response variable among any of the three diets. The Toronto Zoo Small Carnivore Diet is generally preferred by ferret caretakers because of its more even consistency, which makes it easier to feed to ferrets.

Vaccination

Transport of black-footed ferrets across State and international borders may require rabies vaccination, depending on individual State or country regulations. If required, black-footed ferrets over 3 months of age are vaccinated with Imrab® 3 (Merial, Inc., Athens, Ga.). This vaccine is approved for use in domestic ferrets and recommended for yearly revaccination. It is also recommended that ferrets in outdoor pens be vaccinated in areas where rabies is endemic. Rabies vaccination must be by or under the direct supervision of a licensed veterinarian.

Prevention of canine distemper in captive black-footed ferrets has been an important management consideration since the inception of the captive breeding program. Captive ferrets have succumbed to both natural (Williams and others, 1988) and vaccine-induced canine distemper virus (CDV) infections (Carpenter and others, 1976). The search for a safe and effective canine distemper vaccine for use in captive and free-ranging black-footed ferret populations has been a priority for ferret recovery (Wimsatt and others, this volume).

Historically, ferrets in the captive breeding program were vaccinated against CDV with an inactivated virus plus adjuvant. The vaccine was prepared yearly by Dr. M.J.G. Appel of Cornell University. Adjuvant was prepared separately. This vaccine was used until 2002, but no data on duration of immunity and protection against CDV were collected. The recent availability of a commercial, monovalent, canary pox-vectored vaccine for use in domestic ferrets, PureVax® Ferret Distemper Vaccine (Merial, Inc., Athens, Ga.), provided a new possibility for vaccination of captive black-footed ferrets. The vaccine had been tested in the Siberian polecat (*Mustela eversmannii*), a species closely related to the black-footed ferret, with promising results (Wimsatt and others, 2003).

Since management of young black-footed ferrets varies according to their ultimate fate (i.e., release to the wild or captive breeding), we examined several different paradigms of vaccination and the resultant serum neutralization titers. Vaccine used in these studies was a generous donation from Merial. The Wyoming State Veterinary Laboratory in Laramie performed serum neutralization titers.

Three groups of young of the year black-footed ferrets were used. Group 1 consisted of 13 ferrets from multiple litters. These animals were vaccinated intramuscularly with PureVax Ferret Distemper Vaccine. Vaccinations were administered in the right thigh at approximately 60, 74, and 88 days of age. Blood for titers was drawn from the external jugular vein of anesthetized ferrets every 2 weeks, coinciding with vaccinations to minimize handling of young animals. Final blood samples were drawn 2 weeks after the last vaccination. Group 2 included 12 ferrets subjected to vaccination and blood sampling protocols identical to those for group 1, except the PureVax vaccine was given subcutaneously. Group 3 consisted of nine animals subjected to a protocol chosen to approximate the preconditioning of young ferrets for release to the wild. Young preconditioned ferrets are placed in outdoor pens at an early age and often not recaptured for months. Ferrets in this group were vaccinated subcutaneously at 60 days of age and again at 120 days of age. Blood samples were taken at initial vaccination and at 74, 120, and 134 days.

Serum neutralization titers of >1:128 are considered protective (E. Williams, oral commun., 1999). Prior to vaccination, all groups had median titers of <1:8. All ferrets developed protective titers of >1:128 following the second vaccination. Subsequent vaccinations resulted in increased titers. Ten of the ferrets that received intramuscular injections of PureVax were tested 1 year postvaccination, and eight (80 percent) had protective titers.

Results of these studies indicate that black-footed ferrets vaccinated with a minimum of two doses of PureVax Ferret Distemper Vaccine developed protective titers. Three doses of vaccine resulted in increased titers and provided 80 percent of vaccinated ferrets with protective titers up to 1 year later. Based on these results, captive breeding facilities are now encouraged to administer a minimum of two canine distemper vaccinations in young ferrets, beginning at the age of 60 days.

Conclusions

It is apparent that black-footed ferret captive breeding facilities benefit from a flexible management approach. The ability of the program to use adaptive techniques in all areas of ferret management is inextricably linked to the success of reintroduction activities. A stable captive breeding population and an increased number of reintroduction sites have allowed facilities to be more creative in their management decisions. Changes in the program are acceptable only if they do not have a detrimental effect in terms of overall production of animals. Production of kits has been consistent over time, and weaning success continues to improve. Many other changes have been made throughout the history of captive management, including the use of ALPHA-dri™ bedding material (Shepherd Specialty Papers, Watertown, Tenn.), elimination of additional vitamin K supplement, and less labor-intensive dietary management of kits. We will continue to assess our methods on an annual basis and adapt our management in order to provide a stable source of animals to meet the ever-changing needs of the black-footed ferret recovery program.

Use of Reproductive Technology for Black-footed Ferret Recovery

By JoGayle Howard,[1] Rachel M. Santymire,[1] Paul E. Marinari,[2] Julie S. Kreeger,[2] Linwood Williamson,[1] and David E. Wildt[1]

Abstract

Assisted reproductive techniques such as artificial insemination (AI), in vitro fertilization, and sperm cryopreservation have been postulated to be "high-tech" strategies for saving endangered species from extinction; however, there has been limited application of assisted breeding in wildlife management. This report illustrates how reproductive technology has been utilized in an integrated conservation program to save the endangered black-footed ferret (*Mustela nigripes*). Considered extinct until a remnant population was discovered in Wyoming in 1981, the last remaining 18 black-footed ferrets were captured to establish a captive breeding program. In 1988, the U.S. Fish and Wildlife Service developed a Black-footed Ferret Recovery Plan, which emphasized species preservation through natural breeding, development of assisted reproductive technology, and establishment of multiple reintroduction sites, among others. A multi-institutional propagation program has been highly successful. Approximately 250 animals currently reside in six breeding facilities, and >500 black-footed ferrets survive in the wild from reintroduced animals. Methods for semen collection, AI, and sperm cryopreservation were developed first in domesticated ferrets (*Mustela putorius furo*) and the closely related Siberian polecat (*Mustela eversmannii*) and now are used routinely in black-footed ferret management to (1) assess sperm status prior to natural breeding; (2) circumvent cases of sexual incompatibility; (3) enhance reproduction in nonbreeding individuals to retain existing genetic diversity; (4) increase founder representation; (5) establish a genome resource bank to preserve valuable germ plasm; and (6) produce additional offspring for reintroduction. To date, 128 black-footed ferret kits have been produced by AI using fresh or frozen semen. The black-footed ferret represents a model for reproductive biotechniques contributing to a multidisciplinary species recovery and reintroduction program.

Keywords: artificial insemination, assisted reproduction, genetic management, genome resource banking, semen

Introduction

The value of reproductive technologies to ex situ and in situ wildlife management in helping conserve genetic and biological diversity has been considered for years. Assisted reproductive technologies such as artificial insemination (AI), in vitro fertilization (IVF), embryo transfer, and gamete/embryo cryopreservation offer many advantages for managing small populations, largely by ensuring that all genetically valuable animals reproduce (Ballou, 1984; Howard, 1993, 1999; Wildt and Roth, 1997; Wildt and others, 1997). The potential of assisted reproduction could be enhanced further by developing genome resource banks (repositories of cryopreserved sperm, eggs, and embryos), thus preserving valuable genetic material for future generations. The combined use of assisted breeding and germ plasm banks also has potential for infusing genetic material from wild-born individuals into genetically stagnant ex situ populations or even for exchanging genetic material between isolated wild populations (Holt and others, 1996; Wildt and others, 1997).

Despite these advantages, assisted reproduction has not been used consistently in practical wildlife management and conservation, largely for one reason. Until recently, no wildlife species had been sufficiently studied that its reproductive biology was so comprehensively understood that assisted breeding could become routine. It commonly is assumed that reproductive knowledge and techniques established for laboratory rodents, domestic farm species, and even humans are readily adaptable to propagating or overcoming infertility in wild animals (Wildt and others, 2001a,b). This is a misperception because all species have naturally evolved, unique, species-specific reproductive mechanisms, most of which have not yet been elucidated. Without such specific information, no assisted breeding technique can ever become routine.

There still is a need to demonstrate how such reproductive strategies can be used pragmatically. In this paper, we demonstrate how management and conservation of an endangered carnivore, the black-footed ferret (*Mustela nigripes*), have benefited from the application of the reproduc-

tive sciences, including assisted breeding. We assert that the lessons learned from (1) working in partnership with wildlife managers and ex situ breeding institutions, (2) taking a systematic basic and multidisciplinary research approach, and (3) integrating knowledge have helped to recover and reintroduce this endangered species into nature.

Black-footed Ferret Recovery

Between the fall of 1985 and spring of 1987, the Wyoming Game and Fish Department, in cooperation with the U.S. Fish and Wildlife Service, captured the last 18 free-ranging black-footed ferrets from Meeteetse, Wyo., a location known to have sylvatic plague and canine distemper (Forrest and others, 1988; Williams and others, 1988; Thorne and Oakleaf, 1991). In the spring of 1987, captive breeding was successful, and two litters of black-footed ferret kits were born. Given the species' critical status, a recovery plan for ex situ propagation and reintroduction was a high priority. A workshop was held in 1986, facilitated by the Conservation Breeding Specialist Group (CBSG) of the Species Survival Commission of the World Conservation Union (International Union for the Conservation of Nature and Natural Resources). Widespread stakeholder participation was emphasized, and the workshop was attended by representatives from State and Federal wildlife and land management agencies as well as experts in mustelids, small population biology, reproduction, nutrition, veterinary medicine, and genetics. Using workshop information (Seal and others, 1989), the U.S. Fish and Wildlife Service developed an official Black-footed Ferret Recovery Plan in 1988 (U.S. Fish and Wildlife Service, 1988) that emphasized species preservation through research, a multi-institutional ex situ propagation program, and establishment of multiple reintroduction sites. The goal of the ex situ breeding program was to maintain ~240 ferrets (90 males, 150 females) in captivity but in multiple institutions to avoid a catastrophe that might affect any single facility. The aim of the eventual reintroduction program was to establish a total of 1,500 ferrets in at least 10 self-sustaining, free-ranging populations by the year 2010. The wild populations, scattered geographically within the ferret's former range, each were to be composed of at least 30 breeding adults.

Throughout discussions of the ex situ and (eventually) in situ metapopulation structure, the role of sound scientific research, including the potential of reproductive technologies, was always recognized. Managers were especially keen to determine whether such techniques could be useful for evaluating fertility and for developing AI with fresh or cryopreserved spermatozoa, all for the purpose of supporting ex situ breeding and especially avoiding further losses in genetic diversity. One early concept was to establish a black-footed ferret genome resource bank, a frozen repository of spermatozoa from the most genetically valuable males, especially those that failed to reproduce by natural breeding.

Ex Situ Natural Breeding

Intensive management by the Wyoming Game and Fish Department resulted in production of offspring in 1987 and all subsequent years, which allowed dividing the ex situ population into six subcolonies at zoological institutions in North America. The U.S. Fish and Wildlife Service assumed the responsibility of managing the Wyoming breeding facility in 1996 and renamed it the National Black-footed Ferret Conservation Center. Since 1987, the multi-institutional ex situ breeding program has produced >5,100 ferrets (Marinari and Kreeger, this volume) while generating extensive knowledge on ferret biology.

For the past decade, the cooperative effort among the breeding facilities has been guided by the Black-footed Ferret Species Survival Plan® (SSP), a population management strategy of the American Zoo and Aquarium Association designed to maintain a self-sustaining ex situ population while providing animals for reintroduction. Breeding recommendations also are provided in an attempt to equalize genetic representation of the few original wild-born founders. SSP managers determine specific pairs for breeding on the basis of a mean kinship value, a measure of how related an individual is to the remaining population (Ballou and Lacy, 1995; Wisely, this volume). Demographic data, including reproductive lifespan, fecundity, age distribution, and sex ratio, are considered in predicting population stability and growth rate over time. Currently, there are ~250 black-footed ferrets maintained in the SSP program at six locations.

Reintroduction

The ability to produce ferrets in captivity allowed reintroduction to begin in 1991, initially into the Shirley Basin of southeastern Wyoming (Miller and others, 1993; Biggins and others, 1997). A few animals survived over winter, and additional ferrets were released at the same site in subsequent years. In 1995, reintroduction efforts were suspended in Wyoming because of a sylvatic plague outbreak and the loss of vital prairie dog (*Cynomys* spp.) colonies on which the ferrets depend for food and shelter. Subsequent ferret reintroduction sites were established in Conata Basin in South Dakota (Badlands National Park and Buffalo Gap National Grassland in 1994) and Montana (Charles M. Russell National Wildlife Refuge in 1994; Fort Belknap Indian Reservation in 1996). Arizona became the fourth State in the reintroduction program in 1996 with ferret releases in Aubrey Valley. Utah was added as the fifth State in 1999 when ferrets were released in Coyote Basin near the Colorado border. In the fall of 2000, the Cheyenne River tribal lands in South Dakota received ferrets. After extensive planning, a site near Janos, Chihuahua, Mexico, received releases in 2001. Successful reproduction and offspring produced in the wild from released ferrets have been documented at all release sites. Survival of released ferrets has improved because of preconditioning, the exposure of ferrets to large outdoor pens with prairie dog burrow systems and live prey prior to reintroduction. Although success varies, the highest survival has occurred at Conata Basin (South Dakota), with >70 percent of captive-born kits and >90 percent of identified wild-born kits surviving over winter and through spring (T. Livieri, oral commun., 2005). As of fall 2005, the wild population was ~500 black-footed ferrets (T. Livieri, oral commun., 2005).

Development of Reproductive Technologies in Animal Models

Potential benefits of reproductive technologies were recognized from the onset of the recovery program. The recovery plan of 1988 (U.S. Fish and Wildlife Service, 1988), the original and official guide for species rescue, encouraged development of methods for reproductive assessment and assisted breeding. It was realized that AI with fresh or frozen spermatozoa could help retain genetic diversity by ensuring reproduction in every valuable individual that failed to breed naturally. Additionally, a genome resource bank containing cryopreserved spermatozoa could preserve extant genes for the future, as well as assist in the genetic management of this small population.

The National Zoological Park's Conservation & Research Center was invited to take a lead role in studying ferret reproductive biology as well as to participate in the ex situ breeding program. We began our reproductive investigations by using the domestic ferret (*Mustela putorius furo*) and the closely related Siberian polecat (*Mustela eversmannii*) as animal models, first to understand general ferret biology and then to use that knowledge for developing assisted breeding (Wildt and others, 1986). Molecular analyses revealed that the domestic ferret, the Siberian polecat, and the black-footed ferret are taxonomically related (O'Brien and others, 1989). All of these species are seasonal breeders with reproductive activity stimulated by long-day photoperiod (Hillman and Carpenter, 1983; Miller and others, 1988; Mead and others, 1990; Miller and Anderson, 1990; Carvalho and others, 1991). Testis size gradually increases beginning in January or February, peaks from March through June and then gradually declines (Neal and others, 1977). The female's breeding season is monoestrus and restricted to the months of March to June, and is characterized by changes in vaginal cytology and an increase in vulvar size. Finally, these species are classified as induced ovulators, with ovulation occurring ~30 hours after a single copulation or an injection of human chorionic gonadotrophin (hCG) or luteinizing hormone (LH) (Mead and others, 1988).

Extensive studies were conducted on domestic ferrets to develop a reliable approach for collecting, processing, and analyzing fresh or cryopreserved spermatozoa (Curry and others, 1989; Wildt and others, 1989; Howard and others, 1991; Van der Horst and others, 1991). More than 300 electroejaculates from nine males were collected to address the (1) effect of temporal spermatogenesis patterns on sperm viability; (2) comparative effectiveness of vaginal versus uterine insemination via an atraumatic laparoscopic approach; (3) influence of sperm number, dilution medium, and time of hCG administration on pregnancy success, gestation interval, and number of offspring produced; and (4) influence of cryodiluent, freezing method, and thawing temperature on the biological competence of frozen-thawed ferret spermatozoa (Wildt and others, 1989; Howard and others, 1991; Howard, 1999). Such basic studies were crucial to developing reliable assisted breeding techniques. An effective electroejaculation protocol was developed in the domestic ferret to consistently collect high-quality spermatozoa from anesthetized males (table 1). Vaginal insemination was determined to be ineffective for producing offspring; none of 10 females became pregnant after spermatozoa were deposited intravaginally (Wildt and others, 1989). In contrast, transabdominal-intrauterine sperm deposition via laparoscopy resulted in high pregnancy success. Seventeen of 24 ferrets (70.8 percent) inseminated in this fashion became pregnant and delivered live young (Wildt and others, 1989). In addition, embryo transfer was developed in the domestic ferret to nonsurgically transfer preimplantation embryos (Wildt and Goodrowe, 1989; Kidder and others, 1999). Comparative assessments of 12 cryopreservation methods determined that a combination of an egg-yolk/lactose cryodiluent, the pellet freezing method, and a 37°C thawing temperature was effective for freeze-thawing ferret sperm and recovering maximal motility and acrosomal integrity.When this cryomethod was

Table 1. Mean (± SE) ejaculate traits, sperm morphology, and acrosomal integrity in the domestic ferret (*Mustela putorius furo*), Siberian polecat (*M. eversmannii*), and black-footed ferret (*M. nigripes*).

	Domestic ferret (n = 4 males)[a]	**Siberian polecat (n = 8 males)[b]**	**Black-footed ferret (n = 97 males)[b]**
Sperm motility (%)	80.7 ± 1.0[c]	80.6 ± 2.9[c]	51.2 ± 1.8[d]
Sperm progression (0–5; 5 = best)	3.3 ± 0.1	3.0 ± 0.2	2.5 ± 0.1
Normal sperm (%)	67.3 ± 1.3[c]	74.5 ± 2.6[c]	21.0 ± 1.5[d]
Normal intact acrosome (%)	92.4 ± 0.5[c]	96.8 ± 1.0[c]	67.2 ± 2.8[d]

[a] Data based on 52 ejaculates from four males (Howard and others, 1991).

[b] Data based on one ejaculate per male (Howard and others, 1996; J. Howard, unpub. data, 1996).

used, 7 of 10 females (70.0 percent) inseminated in utero with frozen-thawed ferret spermatozoa became pregnant (Howard and others, 1991). Overall, reproductive efficiency was high (70.6 percent) after laparoscopic intrauterine AI with fresh or frozen semen (table 2).

The strategy developed for the domestic ferret was subsequently applied to the Siberian polecat and finally to the black-footed ferret. Although sperm motility traits were similar among the three species, there were significantly fewer structurally normal spermatozoa in the black-footed ferret compared to the domestic ferret and polecat (table 1; Howard and others, 1991, 1996). After cryopreservation and thawing, sperm motility and membrane integrity also were less in the black-footed ferret compared to the other species (Howard and others, 1991, 1996). These differences in sperm viability were assumed to be related to the restricted founder base and reduced genetic variation in the black-footed ferret. Nevertheless, the laparoscopic intrauterine AI technique, developed in the domestic ferret, proved effective in its close relatives. Eight of 10 (80.0 percent) Siberian polecats inseminated with fresh or cryopreserved semen became pregnant (table 2), and this high rate provided the confidence to apply the procedure to the rarer black-footed ferret. Four of six (66.7 percent) black-footed ferrets inseminated with fresh or frozen-thawed semen became pregnant and delivered live young (table 2) (Howard and others, 1996; Howard, 1999).

Table 2. Comparison of laparoscopic intrauterine artificial insemination with fresh or frozen-thawed spermatozoa in closely related ferret species. Data from Wildt and others (1989), Howard and others (1991, 1996), and Howard (1999).

	Domestic ferret (*Mustela putorius furo*)	**Siberian polecat (*Mustela eversmannii*)**	**Black-footed ferret (*Mustela nigripes*)**
Number of females inseminated	34	10	6
Number of pregnant females	24	8	4
Pregnancy rate (%)	70.6	80.0	66.7
Number of kits born	116	42	9
Mean (± SE) number of kits/litter	4.8 ± 0.8	5.2 ± 1.0	2.3 ± 0.6

Assisted Breeding to Enhance Reproduction in Black-footed Ferrets

It soon was realized that the reintroduction goal (1,500 breeding ferrets in 10 free-ranging populations by the year 2010) was not achievable at the current rate of propagation in the ex situ natural breeding program. Early experiences revealed that some animals consistently failed to reproduce. Analysis of breeding records indicated that most females (>90 percent) demonstrated a spring estrus on the basis of vaginal cytology changes (markedly increased numbers of superficial, cornified squamous epithelial cells; fig. 1) (Williams and others, 1992; Brown, 1997); however, there was a high incidence (~40 percent) of pseudopregnancy wherein matings were observed (via video camera) and ovulation was confirmed (by an abrupt decrease in superficial cornified cells), but no pregnancy occurred (Williams and others, 1991). Fecal oestradiol and progestogen metabolite profiles in pregnant versus pseudopregnant females were similar (fig. 1; Brown, 1997), suggesting that endocrine dysfunction was not contributing to the problem.

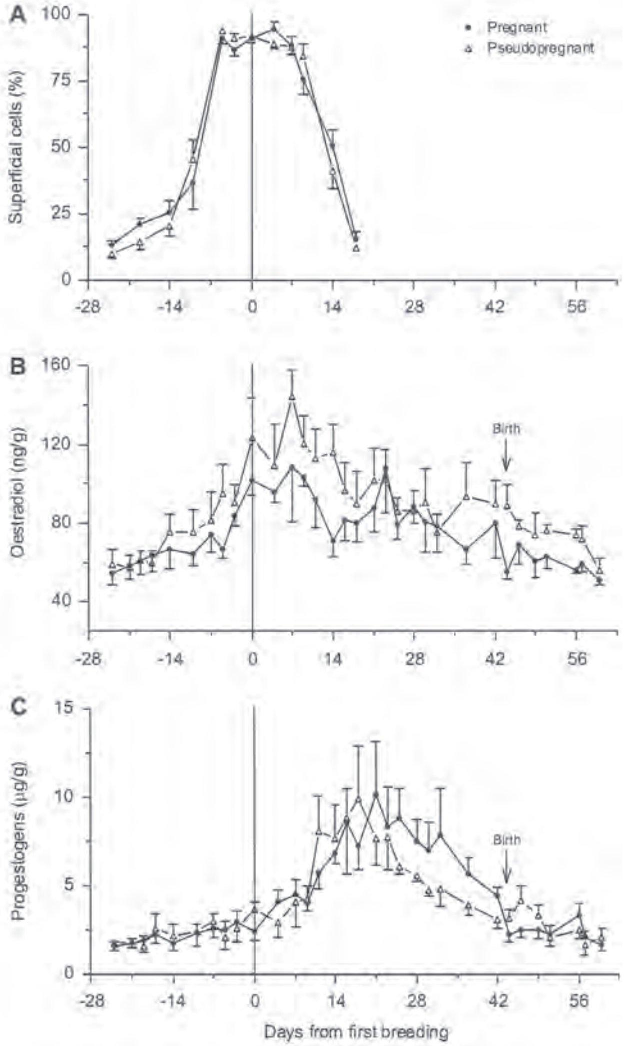

Figure 1. Mean (± SE) percent superficial cells in vaginal lavages (A) and fecal oestradiol (B) and progestogen (C) metabolite concentrations in pregnant (n = 7) and pseudopregnant (n = 9) black-footed ferrets (*Mustela nigripes*). Day 0 is the time of first mating. (From Brown, 1997. Reprinted with permission of the *Journal of Wildlife Management*.)

Interestingly, records analysis indicated that a remarkably high proportion (>50 percent) of prime breeding-age males (1–3 years old) inexplicably failed to sire offspring in captive breeding situations. In 1995, there were 40 such adult males (54.8 percent of the breeding-age male population) that were exposed to prime age, estrual females and yet did not produce young. Simultaneous evaluations also revealed a genetic problem, largely that one of the original wild-born ferret founders was poorly represented in the modern population. This underrepresented lineage had only 43 descendants compared to more than 300 descendants from each of the remaining founder lineages. To help preserve original gene diversity, it was imperative to balance founder representation. This situation was confounded by another challenge in the underrepresented lineage—these males were consistently sexually incompatible with designated mates, largely because of aggression. Together, these issues prompted an examination of the value of reproductive technology and assisted breeding.

At the request of black-footed ferret managers, we agreed to (1) assess reproductive traits and breeding behavior in males with proven versus unproven fertility; (2) establish a genome resource bank containing cryopreserved spermatozoa from the most genetically valuable males; and (3) use AI for improving reproductive efficiency in nonbreeders, all for the ultimate purpose of increasing the number of kits for reintroduction. A survey was conducted in 1996 and 1997 to determine the precise number of prime breeding-age males not siring offspring and the reasons for failed reproduction. As in 1995, a high percentage of 1- to 3-year-old males did not sire young in 1996 (38 of 69 males, 55.1 percent) or 1997 (35 of 60 males, 58.3 percent) (Wolf and others, 2000b). Semen evaluations determined that there were no differences in sperm concentration, motility, or morphology between proven and unproven breeders (Wolf and others, 2000b). A detailed review of breeding data revealed that males failed to reproduce because of improper breeding position, behavioral incompatibility (e.g., aggression), and poor testes development (Wolf and others, 2000b). As much of the problem was behaviorally based, we speculated that assisted reproduction could be beneficial for improving reproductive efficiency.

A systematic strategy was used to establish the genome resource bank. Using the computer software program (SPARKS; International Species Information System, Eagan, Minn.) developed for SSP programs, sperm donors could be selected on the basis of founder representation and mean kinship (Ballou and Lacy, 1995; Johnston and Lacy, 1995; Wisely, this volume). High-priority black-footed ferret males were selected for inclusion in the bank, with semen samples collected and cryopreserved for AI (as part of routine management) or for long-term storage (as a hedge repository of valuable genes).

At the National Zoological Park's Conservation & Research Center, the natural breeding program for black-footed ferrets was modified to include AI. The goals were to (1) produce offspring from behaviorally incompatible animals, especially nonbreeding males, to meet reintroduction demands and (2) increase founder representation in the underrepresented lineage. In achieving these goals, other opportunities arose, including examining the impact of male age on reproductive success. From 1996 through 2003, nonbreeding males of high genetic value were chosen as candidates for assisted reproduction. Overall, 66 females were monitored for natural estrus and were administered hCG or LH (to induce ovulation) 5 to 7 days after maximal vulvar swelling and >90 percent superficial cornified vaginal cells. Twelve to 20 hours later, each female was anesthetized and, under laparoscopic observation, inseminated in utero with fresh or frozen-thawed spermatozoa. Five of six (83.3 percent) females inseminated with semen from founder descendants became pregnant and produced 16 kits (table 3). Males were determined to produce excellent quality semen through 5 years of age, 2 years longer than the normal female reproductive life span (Wolf and others, 2000a). Eight of 11 (72.7 percent) females inseminated with semen from 5-year-old males produced 17 kits (table 3). A total of 28 of 49 (57.1 percent) females gave birth to 95 kits following AI with semen from genetically valuable, nonbreeding males (table 3). Overall, AI resulted in 128 additional black-footed ferret kits, offspring that never would have been born from natural mating.

There were other by-products as well. For example, we observed that a high proportion of 1-year-old males produced aspermic (no sperm) ejaculates during the breeding season (Howard and others, 1998). These males experienced increases in seasonal testicular tumescence (albeit somewhat slower than elders; fig. 2) and copulated with females; however, systematic seminal evaluations revealed that these yearlings produced spermic ejaculates at least 4 weeks later in the breeding season than older counterparts (fig. 2). This asynchrony in sperm

Table 3. Use of laparoscopic artificial insemination to enhance propagation in nonbreeding founder descendants, 5-year-old males, and genetically valuable male black-footed ferrets (*Mustela nigripes*) from 1996 through 2003.

	Founder descendants[a] **(*n* = 3 males)**	**5-year-old males**[b] **(*n* = 5 males)**	**Genetically valuable males**[c] **(*n* = 27 males)**
Number of females inseminated	6	11	49
Number of pregnant females (%)	5 (83.3)	8 (72.7)	28 (57.1)
Number of kits born	16	17	95

[a] Males were descendants of a wild-caught founder whose genetic lineage was underrepresented in the ex situ population.

[b] Reproductive competence was assessed in 5-year-old males.

[c] Despite numerous breeding opportunities, reproductive failure in these genetically valuable males was due primarily to behavioral incompatibility (aggression or shyness) or inappropriate breeding position.

production probably influenced the incidence of pseudopregnancy because aspermic males can induce ovulation following copulation. This was an important observation with significant implications for routine ferret management. Until this finding, males used for breeding were selected on the basis of enlarged testis size. Now, only males with spermic electroejaculates are allowed access to females for natural breeding, and introducing this simple semen assessment technique to the management protocol in 1998 resulted in a striking 20 percent increase in pregnancy success and 59 additional kits available for reintroduction (table 4).

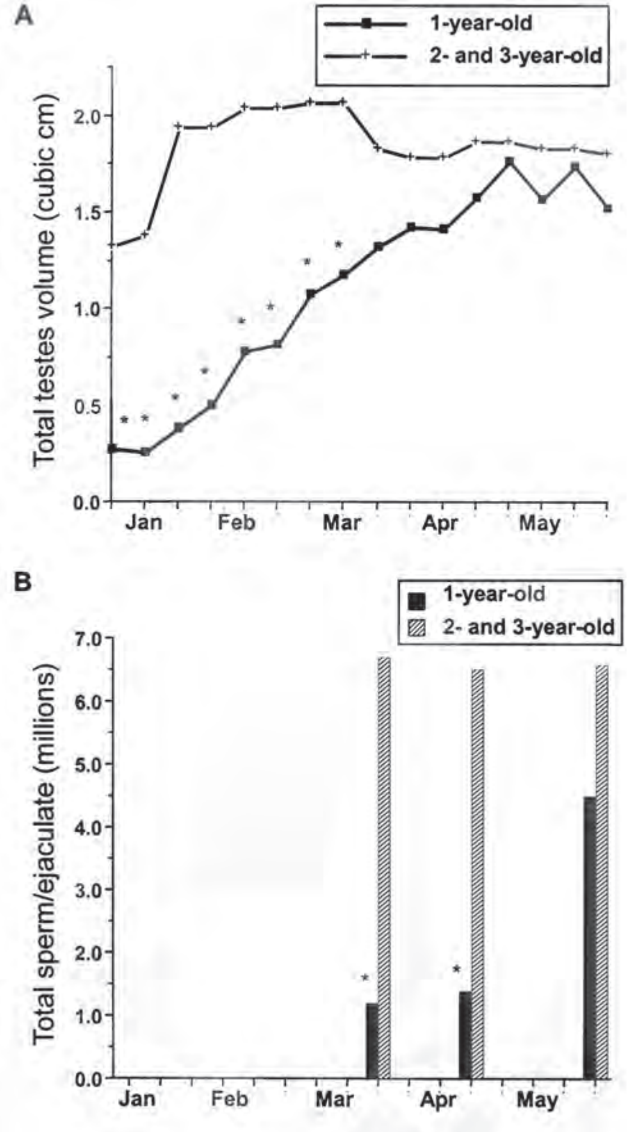

Figure 2. Influence of age on testes development (A) and total sperm/ejaculate (B) in 1-year-old versus 2- and 3-year-old male black-footed ferrets (*Mustela nigripes*). Asterisks indicate differences ($P < 0.05$) between age groups within a month.

Table 4. Propagation in the black-footed ferret (*Mustela nigripes*) using enlarged testes versus spermic ejaculate as the criterion for selecting males for natural breeding.

	Enlarged testes	Spermic ejaculate
Number of females bred	84	86
Number of litters	50	69
Pregnancy success (%)	59.5	80.2
Number of kits born	190	249

Priorities for the Future

The black-footed ferret is a provocative example of how reproductive technologies integrated with both ex situ and in situ management plans can benefit species conservation. The positive results are evidence that reproductive techniques are valuable for (1) generating new knowledge of relevance to natural and assisted breeding and (2) producing living, genetically valuable offspring useful for breeding stock and/or reintroduction. Priorities for this species extend far beyond reproductive biology; adequate survival after reintroduction continues to be essential to the black-footed ferret's future. Urban sprawl, sylvatic plague, and poisoning of prairie dogs appear to be never-ending, severe threats. Today, only 2 percent remains of the ~100 million acres of the original prairie dog ecosystem of the Great Plains (Miller and others, 1996). Monitoring for presence of sylvatic plague as well as canine distemper is essential for long-term protection of both prairie dogs and ferrets. Research into the development and use of a sylvatic plague vaccine is ongoing (Rocke, this volume). Even when a vaccine becomes available, there will be enormous distribution challenges. Also, persistent poisoning campaigns and recreational shooting continue to contribute to the collapse of the prairie dog ecosystem.

Finally, a high priority will continue to be education programs, which play a crucial role in public awareness of black-footed ferret conservation issues. Currently, over 30 zoos and wildlife agencies sponsor educational exhibits, often using "ambassador" black-footed ferrets. Gaining public support, especially from landowners who consider prairie dogs pests, is critical to reintroduction success. Many landowners continue to have serious concerns about endangered species, especially perceived governmental interference and restrictions on land use (Reading and Kellert, 1993; Miller and others, 1996). A key factor facilitating landowner support for ferrets has been the designation of the reintroduced population as experimental and nonessential under the Endangered Species Act (see Lockhart and others, this volume, for additional information). Although resulting in a lower level of protection for released ferrets, this strategy has gained local rancher and farmer cooperation while providing some assurance that reintroduced ferrets and traditional land uses can be compatible.

Conclusion

It is apparent that reproductive sciences can play a vital role in a holistic, integrated conservation program to save an endangered species. The contemporary story of the black-footed ferret illustrates the potential for species recovery and reintroduction based on partnerships and multidisciplinary, sound science. Perhaps most important has been the cooperative feature, collaboration among over 30 organizations, including State and Federal agencies, conservation groups, and zoos, that worked together to return ferrets to their former grassland habitats of the Great Plains. Reproductive technologies, including AI and a genome resource bank, have been integrated successfully into the black-footed ferret recovery program to maintain genetic diversity, enhance reproductive efficiency, and produce additional animals for reintroduction.

Acknowledgments

The authors acknowledge the U.S. Fish and Wildlife Service and the staff of the National Black-footed Ferret Conservation Center for continued support. We thank graduate students Karen Wolf and Rachel Santymire and Dr. Janine Brown for generating some of the data presented. We are indebted to Drs. Julie Kreeger and Mitchell Bush for animal health and veterinary assistance and to Linwood Williamson and the National Zoological Park's Conservation & Research Center animal keeper staff for animal management and care.

The Genetic Legacy of the Black-footed Ferret: Past, Present, and Future

By Samantha M. Wisely[1]

Abstract

The black-footed ferret (*Mustela nigripes*) evolved in Beringia sometime in the early to middle Pleistocene. By 35,000 years before present the species was distinct from its sister taxon, the Siberian polecat (*Mustela eversmannii*). Genetic analysis revealed that historical populations had restricted gene flow prior to human disturbance, which had consequences for the conservation of genetic diversity in the species. Most genetic diversity in the species was lost when Great Plains populations were extirpated, leaving the last surviving population genetically distinct and depauperate. Further genetic losses occurred when almost half of the animals captured from the last population failed to breed in captivity. Once established in captivity, however, maintenance of remaining genetic diversity was within the goals of genetic management mandated by the recovery plan. Reintroduced populations of black-footed ferrets maintained genetic diversity, but were slightly differentiated from one another because of differences in population founders. Wild-born animals were less inbred than captive-released animals, suggesting that inbreeding avoidance mechanisms may operate in the wild. Although much diversity has been lost, inbreeding depression has not been confirmed. Future management efforts should maintain vigilance to conserve remaining genetic diversity both in captivity and in reintroduced populations.

Keywords: captive breeding, genetic diversity, genetic drift, Pleistocene refugia, population bottleneck, reintroduction

Introduction

Eighteen years have passed since the first genetic study of the black-footed ferret (*Mustela nigripes*) was completed (Kilpatrick and others, 1986). Although techniques have advanced and our understanding of genetic processes has expanded, the story revealed by this species' genes remains unwaveringly clear: the genetic uniformity measured in this species is unprecedented and rivaled by perhaps only one other carnivore, the cheetah (*Acinonyx jubatus*; O'Brien and others, 1983). Unlike the cheetah, however, whose Holocene population bottleneck remains shrouded in mystery, the black-footed ferret's demise was witnessed and documented by museum collectors, commercial trappers, animal control agents, and biologists (Anderson and others, 1986), providing a clear understanding of the demography of the bottleneck. Although the dramatic nature of the bottleneck was unfortunate for conservation of the species, it provides conservation-based science with the opportunity to study the genetic consequences of rapid and dramatic population loss outside of the laboratory setting.

Population bottlenecks occur when population size is rapidly reduced; the severity of a bottleneck depends on the minimum population size attained and the duration of time it remained small (Frankham and others, 2002). Although the immediate consequence of small population size is increased risk of extinction as a result of demographic stochasticity, long-term consequences result from reduced genetic diversity and increased inbreeding (Frankel and Soulé, 1981). By increasing the expression of deleterious alleles, inbreeding reduces individual fitness, further increasing the likelihood of extinction. Inbreeding depression caused by a population bottleneck has been documented in a variety of species, including the Florida panther (*Puma concolor coryi*; Roelke and others, 1993), fritillary butterflies (*Melitaea cinxia*; Saccheri and others, 1998), and koalas (*Phascolarctos cinereus*; Seymour and others, 2001). Reduced genetic diversity also has the insidious and difficult to measure effect of reducing a species' ability to adapt to a changing environment. Examples in the literature are few but include endemic rainforest fruitflies (*Drosophila* spp.; Hoffman and others, 2003).

The black-footed ferret experienced serious population decline beginning in the mid- to late 1800s as people migrated west and converted grasslands to agriculture. By 1981 only one population remained, and the species reached its nadir in 1987 when the last of 18 individuals were taken into captivity from Meeteetse, Wyo. (Clark, 1994). This was the first time the U.S. Fish and Wildlife Service (FWS) had managed an endangered species by removing all living individuals from the wild. Ironically, FWS made that decision twice in 1987, when the last remaining California condors (*Gymnogyps californianus*; Seal, 1989; Snyder and Snyder, 2000) were also removed from the wild and placed in a captive breeding program. Unfortunately, animal husbandry practices were not fully

---

established in the initial years of captive breeding, and only seven founding ferrets are represented in the current captive population (Garell and others, 1998). Nonetheless, more than 4,000 individuals have been produced, and today approximately 240 animals exist in captivity and 500 in the wild. With a founder genome equivalent (the number of unique genomes represented in the current population) of 4.1 (Russell and others, 1994), the species currently contains a fraction of the genetic diversity once present.

Several demographic events transpired to reduce the population size of this species. Habitat conversion, poisoning campaigns aimed at prairie dogs (*Cynomys* spp.), and exotic diseases decreased the population by 99 percent over approximately 100 years. In the last historical population, simultaneous epizootics of canine distemper virus and sylvatic plague (caused by the bacterium *Yersinia pestis*) caused dramatic population decline in less than a year. In order to understand the consequences of these demographic events, one must first understand the context in which they occurred. How much genetic diversity did the species have prior to anthropogenic disturbance? How much genetic diversity did black-footed ferrets have prior to the bottleneck of the Meeteetse population? How did population structure affect the rate of loss of genetic diversity? Once ferrets were taken into a captive breeding program, how well was the remaining genetic diversity conserved? Finally, as reintroduced populations continue to be established, it is crucial to understand how the process of reintroduction affects genetic diversity and structure. In the following chapter, I synthesize what is known about the genetic legacy of this species as it passed through the processes of population bottleneck, captive management, and reintroduction.

Pleistocene Colonization of North America

The black-footed ferret is a relatively recent immigrant to North America via the Bering land bridge (Youngman, 1994). The earliest fossil record of a black-footed ferret in North America is from Cathedral Cave in eastern central Nevada (Owen and others, 2000). This specimen dates approximately 800,000 years before present based on paleomagnetic data and biochronology of arvicoline rodents collected at the site (Owen and others, 2000). In support of a middle Pleistocene invasion, molecular clock estimates based on 41 isozymes suggest that the black-footed ferret split from its sister species the Siberian polecat (Mustela eversmannii) between 0.5 and 2 million years ago (O'Brien and others, 1989). Thus it appears that the ancestral black-footed ferret crossed the land bridge approximately 1 to 2 million years ago. The species gained access to the grasslands and shrublands of North America via an interglacial, ice-free corridor (Anderson, 1989; Youngman, 1994) and was established at least as far south as Nevada by 800,000 years ago. Once established, the species spread rapidly throughout the Great Plains. By 35,000 years before present the black-footed ferret was morphologically distinguishable from the Siberian polecat. In fact, the two species appear to have existed sympatrically; fossils of both species found in eastern Beringia as recently as 35,000 years ago suggest a period of secondary contact after differentiation (Youngman, 1994).

Molecular data suggest that black-footed ferret populations had restricted gene flow and high population differentiation that was influenced by both natural history and the ebb and flow of Pleistocene glaciers (Wisely and others, 2002). Genetic variation becomes partitioned among subpopulations when isolating mechanisms, such as Pleistocene glaciers and unsuitable habitat, prevent gene flow and increase genetic drift (Frankham and others, 2002). Using microsatellite markers, Wisely and others (2002) reported an average F_{ST} of 0.53. F_{ST} is a pairwise measure of genetic variation that is partitioned among populations. This parameter measures genetic structure and gene flow between subpopulations and ranges in value from 0 (no allelic differentiation or structure) to 1 (maximum allelic divergence). The value found for black-footed ferrets is one of the highest reported for a mammalian carnivore and likely reflects aspects of their unusual ecology. Their diminutive body size, coupled with their semifossorial lifestyle, likely limited their dispersal capabilities (when compared to other carnivorans) and therefore induced genetic drift within populations and created genetic differentiation among populations (Wisely and others, 2002). Subpopulation isolation was likely exasperated by habitat barriers that formed during glacial maxima.

Historical Genetic Diversity and Structure

The historical population structure of the black-footed ferret in North America greatly influenced the amount of genetic diversity that was lost. The magnitude of loss of genetic diversity was exasperated by the especially isolated nature of the last population. Located on the periphery of the historical distribution near the town of Meeteetse, Wyo. (Hillman and Clark, 1980), this population was likely a refugium during the last glacial maximum and remained isolated from other populations throughout the Holocene (Wisely and others, 2002). Measures of genetic distance used to estimate genetic differences among black-footed ferrets from three historical populations confirm that the Meeteetse population was the most highly differentiated and therefore isolated of the three populations (Wisely and others, 2002). Thus, when ferret populations from the Great Plains were extirpated, the majority of genetic diversity found in the species was lost (table 1, fig. 1). Indeed, the Meeteetse population was different enough from other ferret populations that the addition of even four individuals from Mellette County, S. Dak. (the second to last population of black-footed ferrets), would have increased allelic diversity in extant ferrets by 50 percent (Wisely and others, 2002).

Table 1. Observed (H_o) and expected (H_e) heterozygosities for 14 microsatellite loci in black-footed ferrets (*Mustela nigripes*) from Wyoming, South Dakota, and Kansas combined (representing the species prior to disturbance; $n = 20$) and from Wyoming only ($n = 12$), and HWE *P*, the probability associated with an exact test of Hardy-Weinberg equilibrium. Seven of 14 loci were monomorphic in the Wyoming population. HWE was tested only in polymorphic loci from Wyoming. (From Wisely and others, 2002. Diversity and Structure in Captivity

Although Meeteetse animals were first captured in 1985, successful breeding was not achieved until 1987 (Clark, 1994). Of the 18 animals that survived in captivity, only 8–11 founders (unknown paternity of some wild-caught litters created some uncertainty as to the exact number) were initially represented in the pedigree; 20 years later, only 7 founders are represented in the extant population (Garell and others, 1998). The consequences of this bottleneck were measurable. Had 5 more of the original 18 ferrets bred successfully, genetic diversity of the extant population would have increased by 30 percent (fig. 1; Wisely and others, 2002). Once animal husbandry was understood and disease concerns were alleviated, the population quickly expanded, and the remaining genetic diversity was conserved (Wisely and others, 2003).

The dramatic loss of approximately 90 percent of the species' genetic diversity necessitated conservation of that which remained. Because all captive populations are susceptible to problems associated with small population size, including inbreeding, inbreeding depression, and genetic drift (de Boer, 1994), management of the remaining genetic variation was a high priority (Ballou and Oakleaf, 1989). Various approaches have been used to maximize retention of genetic variability; for the black-footed ferret, the mean kinship strategy augmented with line breeding of underrepresented founders was recommended (Ballou and Oakleaf, 1989). Briefly, mean kinship strategy finds suitable breeding pairs that maximize the representation of the most underrepresented founders of the captive population. Over time, this strategy is predicted to maximally conserve genetic diversity. Empirically, it appears that this strategy has succeeded in adequately preserving genetic diversity. Founders' genes were more evenly represented in the captive population in 1999 than in the first generation of captive black-footed ferrets (fig. 2; Wisely and others, 2003), and even representation of founders maximally conserves genetic diversity in a pedigreed population. Likewise, a pedigree-based estimate of loss of heterozygosity was 12 percent, which meets the goal established by the American Zoo and Aquarium Association's Species Survival Plan® of retaining 80 percent of the genetic diversity of the founding population for 25 years (Garell and others, 1998). Molecular-based estimates revealed no loss of allelic diversity; all alleles present in the founders were present in the extant population (Wisely and others, 2003).

Diversity and Structure of Reintroduced Populations

Once captive-born animals were released into the wild, further challenges faced the recovery program. A successful captive breeding reintroduction program involves substantive

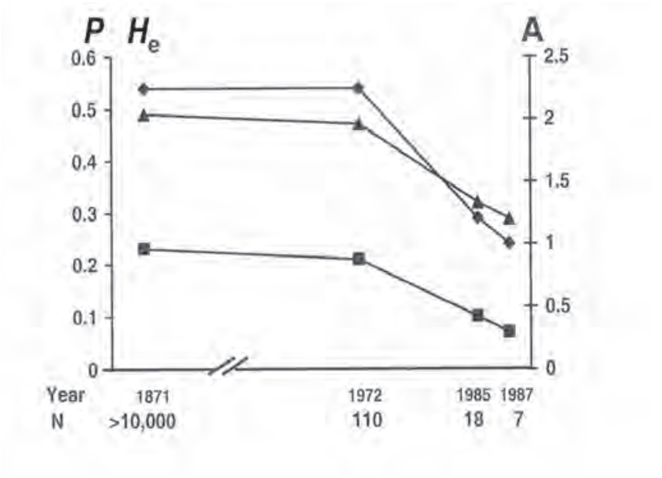

Figure 1. A timeline of genetic diversity in the black-footed ferret (*Mustela nigripes*). A, the average number of alleles per locus (triangle); H_e, expected heterozygosity (diamond); and P, the proportion of polymorphic loci (square) were at their highest values in 1871. In 1972 only two populations remained, in Mellette County, S. Dak., and Meeteetse, Wyo. Note that although many populations throughout the Great Plains were extirpated, genetic diversity did not appreciably decrease. With the loss of the Mellette County population, substantial amounts of genetic diversity were lost. Only the Meeteetse population remained in 1982. Further loss of genetic diversity occurred because of a bottleneck in the last population from 1982 to 1987. (From Wisely and others, 2002. Reprinted with permission of Oxford University Press, Oxford, U.K.)

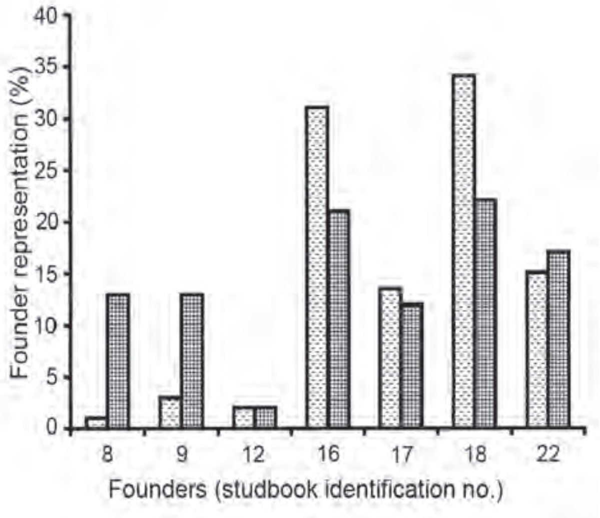

Figure 2. Founder representation in the first generation of captive breeding (i.e., all the direct descendants) (dotted bars) and in 1999, after 14 years of captive breeding (cross-hatched bars) of black-footed ferrets (*Mustela nigripes*). Only founders with genes represented in the extant population are considered. (From Wisely and others, 2003. Reprinted with permission of Wiley-Liss, Hoboken, N.J.)

but reconcilable tradeoffs. Demographic and genetic attributes affect the success of reintroduced populations (Jiménez and others, 1994; FitzSimmons and others, 1997), yet selection of animals for release removes them and their potentially unique genes from the captive breeding pool. This sets up a potential conflict between the goals of captive breeding and reintroduction (Earnhardt, 1999). Because of the tenuous nature of the early captive breeding program and the recognition that captive breeding would need to be maintained for many years, inbred animals and animals with a mean kinship >0.125 were designated for release (Ballou and Oakleaf, 1989). This strategy would maximize retention of genetic diversity in the captive population.

Inbreeding in 1991, estimated from pedigree analysis, was higher in released captive-bred animals ($F = 0.092$) than in animals retained in the captive population ($F = 0.052$; Russell and others, 1994), as would be expected by the designation criteria for animals retained versus released from the captive population. By 1999, overall inbreeding was higher (as would be expected in a small, closed population), but the difference between captive breeders and captive releases was negligible ($F = 0.12$ and 0.11, respectively; Wisely and others, 2003). The gap between breeders and releases was closed because founder genes were more evenly represented in the 1999 than in the 1991 captive population (fig. 2), resulting in a panmictic population. Equal founder representation reduced the variance in mean kinship of individuals, which in turn decreased the difference in genetic composition between breeders and releases (Wisely and others, 2003).

As of 1999, no difference in genetic diversity had been detected between captive-reared releases and their wild descendants from Charles M. Russell National Wildlife Refuge, Mont., and Conata Basin, S. Dak. (table 2; Wisely and others, 2003). This finding suggests that initial releases and subsequent augmentation were sufficient to halt drift-induced losses in diversity. Small but statistically significant population differentiation ($F_{ST} = 0.09$, 95 percent CI = 0.04–0.13) between wild descendants of two reintroduced populations suggested that even with augmentation of captive animals to the reintroduced population, these two populations had measurable genetic differences attributable to random differences in the founders of each reintroduction site (Wisely and others, 2003). Whether this statistically significant difference is also biologically significant is difficult to say (Hedrick, 1999). It is likely, however, that, as populations grow and augmentation ceases, continuing genetic drift will decrease genetic diversity within populations and increase genetic distance among populations.

Because wild-born animals were descended from animals with higher than average mean kinship and inbreeding (as calculated from the pedigree and estimated from microsatellites), it was predicted that the offspring would be inbred. In fact, this was not the case (table 2; Wisely and others, 2003). This result was surprising inasmuch as free ranging populations were smaller than the captive population, released animals were the descendants of overrepresented individuals,

Table 2. Measures of genetic diversity, H_o, the observed heterozygosity, and H_e, the expected heterozygosity, for five groups of black-footed ferrets (*Mustela nigripes*), and HWE *P*, the probability of heterozygote deficiencies (an indicator of inbreeding) within groups. H_e and H_o values were averaged over the seven microsatellite loci that were polymorphic in the historical Wyoming population. Each of the seven loci had two alleles per locus in each group of ferrets. Both captive breeders and captive releases showed evidence of inbreeding as predicted by pedigree-based methods. (From Wisely and others, 2003. Reprinted with permission of Wiley-Liss, Hoboken, N.J.)

Group	*n*	H_o	$H_e \pm 2$ SE	HWE *P*
Founders	7	0.40	0.33 ± 0.14	0.76
Captive breeders	29	0.32	0.41 ± 0.12	0.03
Captive releases	36	0.31	0.38 ± 0.14	0.01
Wild, Montana	81	0.33	0.33 ± 0.14	0.47
Wild, South Dakota	41	0.43	0.38 ± 0.12	0.87

and litter mates often were released together. A possible explanation for the lack of inbreeding in the wild populations is a behavioral response of inbreeding avoidance. Several researchers have proposed that closely related individuals avoid mating in such taxa as black-tailed prairie dogs (*Cynomys ludovicianus*; Hoogland, 1982), olive baboons (*Papio anubis*; Packer, 1979), and the marsupial genus *Antechinus* (Cockburn and others, 1985). Given that the reintroduced founding populations were small and that black-footed ferrets avoided close kin matings, survival and reproduction of founding populations may have been less than optimal as reintroduced individuals avoided breeding with one another and dispersed to find unrelated mates (Wisely and others, 2003).

The Future

The consequence of dramatic loss of genetic diversity in a species is unclear. Some taxa, such as felids, are highly susceptible to inbreeding depression, while other taxa appear unaffected (Ralls and Ballou, 1983; Lacy, 1997). Small, inbreeding populations have a higher rate of expression of deleterious alleles, which can lead to extinction when the forces of genetic drift are greater than natural selection. When selection exceeds drift, however, small, inbreeding populations can purge deleterious alleles, ultimately making them less susceptible to inbreeding depression. To date, no physiological abnormalities have been linked to inbreeding depression in black-footed ferrets, although abnormalities exist (Howard and others, this volume). Indeed, fecundity of females (measured as kits surviving per litter) was virtually the same (3.1–3.3 kits per female) for animals observed in the historical populations of Mellette County, S. Dak. (Hillman and Carpenter, 1980), and Meeteetse, Wyo. (Forrest and others, 1988), and the reintroduced population in Conata Basin, S. Dak. (U.S. Department of Agriculture, 2000).

Without question the two biggest hurdles to recovery of this species are lack of suitable habitat for reintroduction and sylvatic plague (Conservation Breeding Specialist Group, 2004). Where ample, plague-free habitat exists, populations appear to flourish despite reduced genetic diversity. The dramatic loss of genetic diversity in this species should not discourage biologists from planning for recovery. With careful management of remaining genetic resources, this species will likely persist. Continued, vigilant conservation of genetic diversity in the captive population will be critical to the long-term success of this recovery effort. Likewise, genetic management of the reintroduced populations will be critical once populations become self-sustaining. Currently, only two populations are self-sustaining: those of Shirley Basin, Wyo., and Conata Basin, S. Dak. All other reintroduction sites rely on yearly augmentation to maintain their populations. Translocations for genetic augmentation may be necessary if reintroduced populations lose genetic diversity because of drift.

The dramatic loss of genetic diversity in this endangered species should serve as a reminder to conservation practitioners that proactive management of population structure (conserving as many individuals from as many geographic locations as possible) can have a profound effect on the conservation of genetic resources for a species. Furthermore, rapid breeding of as many founders as possible within the first few generations of captive breeding will maximize the retention of the remaining genetic diversity and increase the likelihood of persistence into the future.

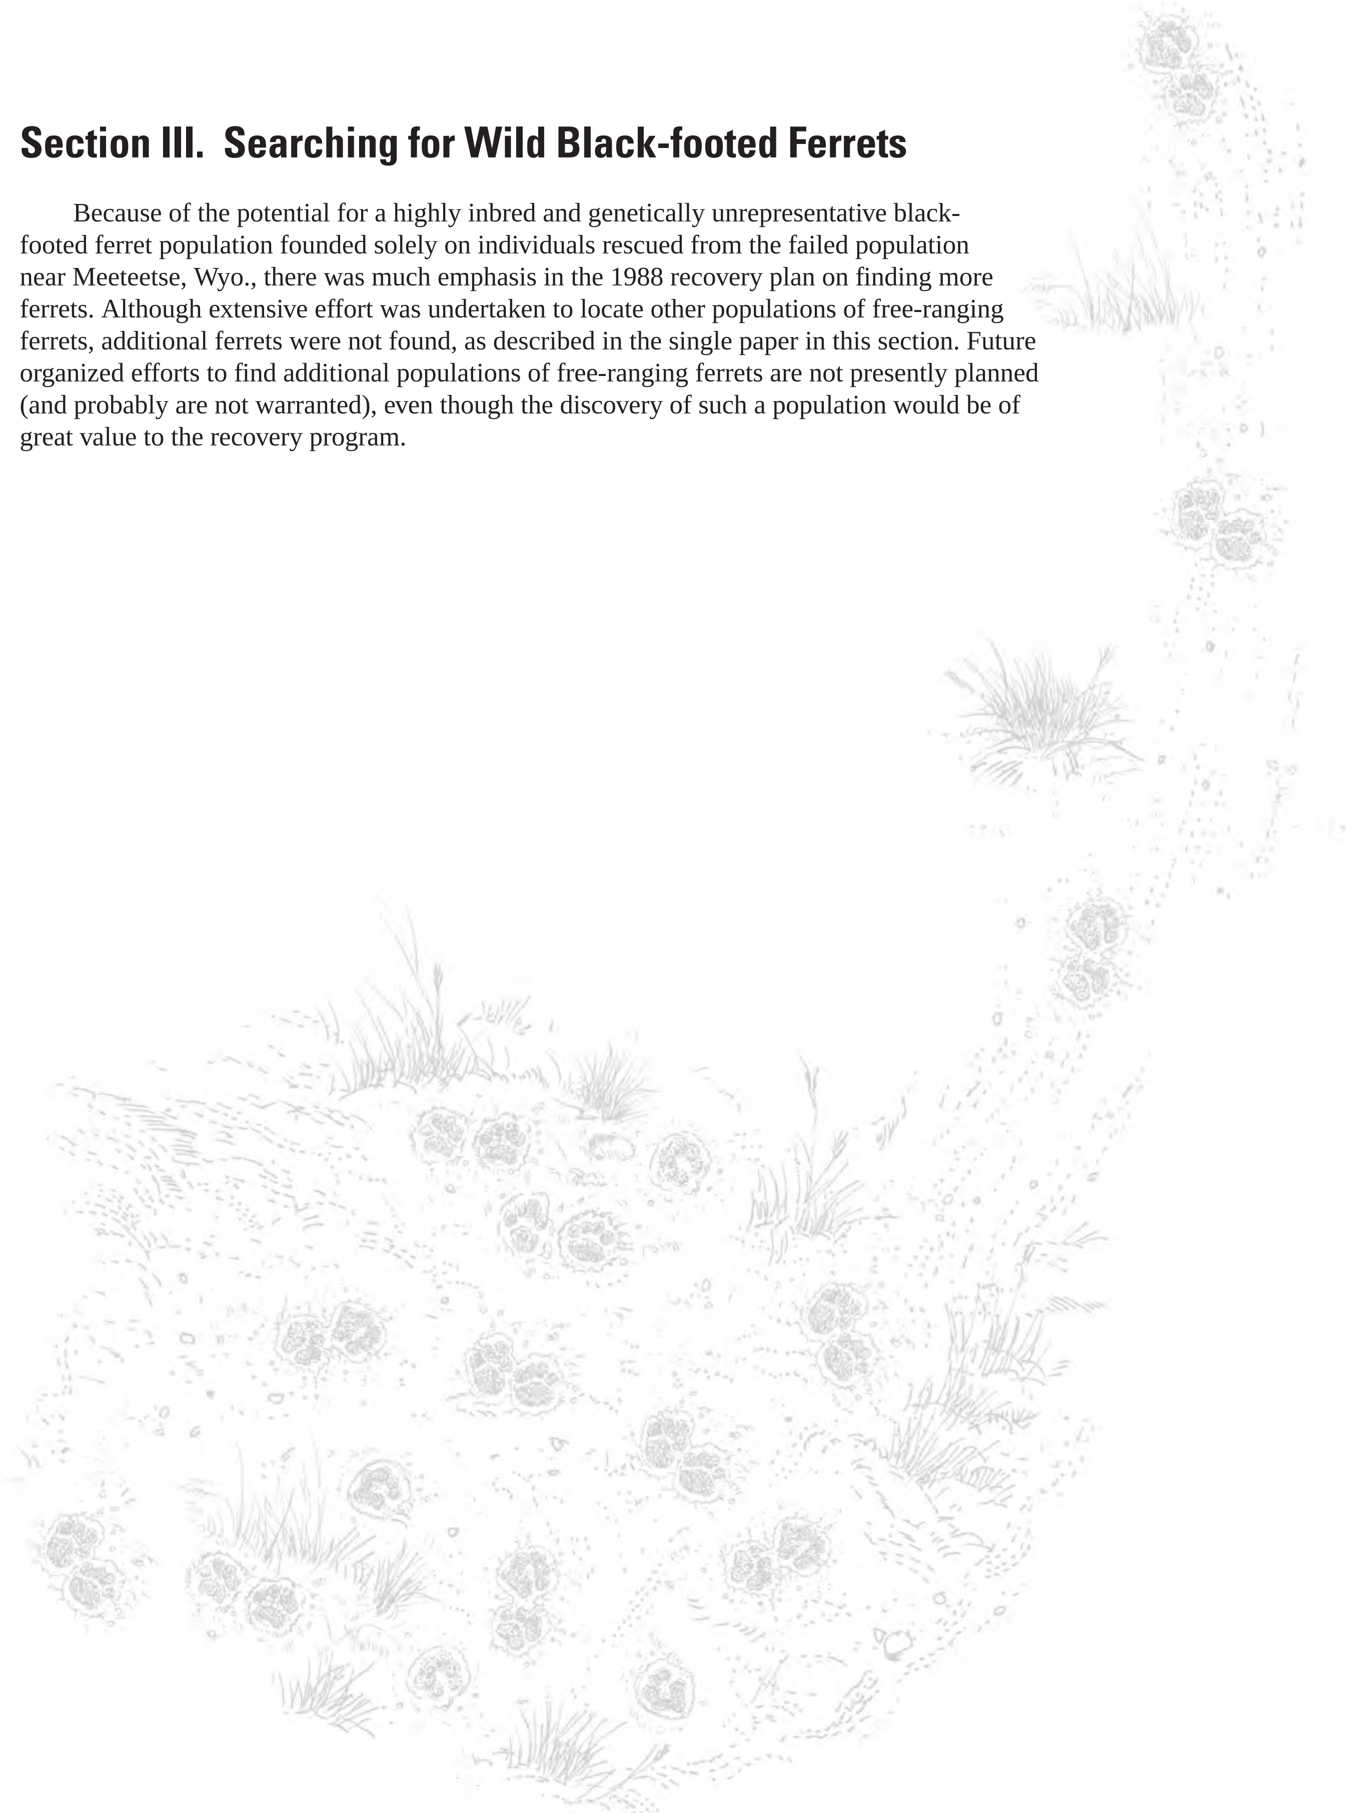
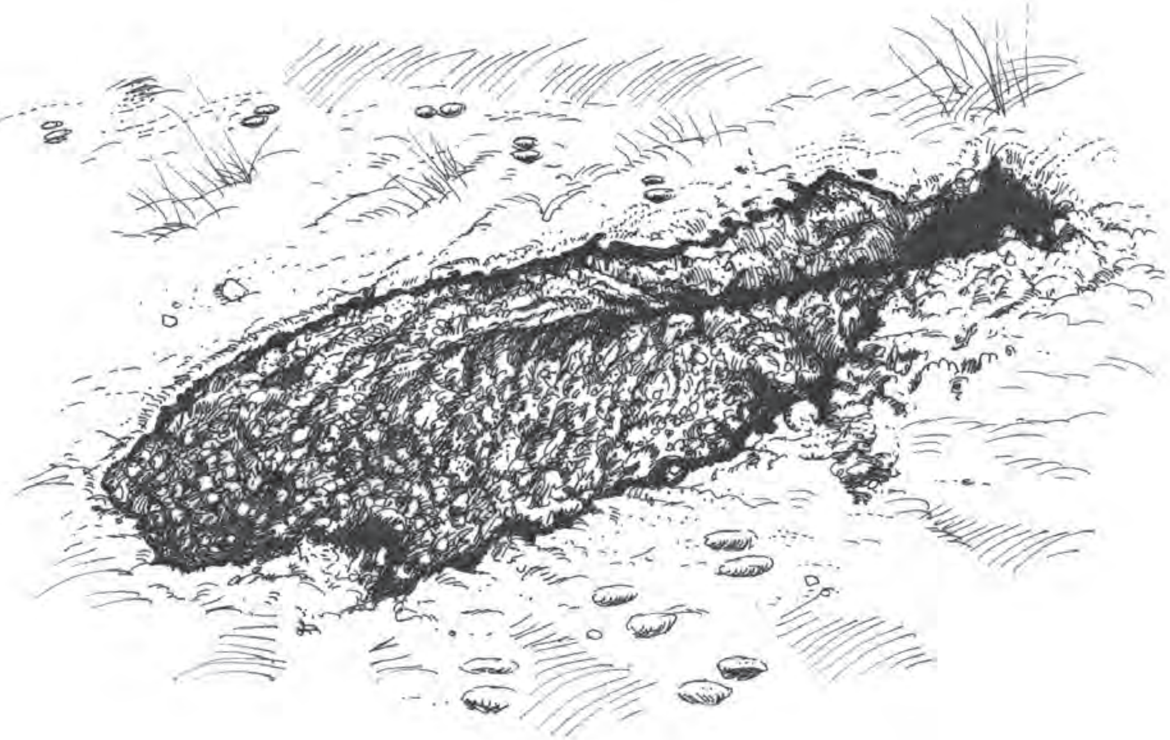
Section III. Searching for Wild Black-footed Ferrets

Because of the potential for a highly inbred and genetically unrepresentative black-footed ferret population founded solely on individuals rescued from the failed population near Meeteetse, Wyo., there was much emphasis in the 1988 recovery plan on finding more ferrets. Although extensive effort was undertaken to locate other populations of free-ranging ferrets, additional ferrets were not found, as described in the single paper in this section. Future organized efforts to find additional populations of free-ranging ferrets are not presently planned (and probably are not warranted), even though the discovery of such a population would be of great value to the recovery program.





A History of Searches for Black-footed Ferrets

By Louis R. Hanebury[1] and Dean E. Biggins[2]

Abstract

Studies of wild populations of black-footed ferrets (*Mustela nigripes*) in South Dakota in the 1960s, in Wyoming in the 1980s, and of captive-bred ferrets reintroduced to unoccupied habitat in Wyoming, South Dakota, and Montana in the 1990s contributed to our understanding of ferret behavior and improved techniques to find ferret populations. We chronicle the efforts of private, State, and Federal institutions that used these techniques to locate remaining populations of ferrets. During the 1980s, a renewed survey effort and solicitation of new sightings, coupled with a monetary reward program, failed to locate ferrets. We believe that the probability of finding ferrets from noncaptive stock is already small and diminishes with each passing year.

Keywords: black-footed ferret, *Mustela nigripes*, reward, sighting, spotlighting, survey technique

Introduction

The original recovery plan for the endangered black-footed ferret (*Mustela nigripes*) was approved in June 1978, and a revised recovery plan was approved in August 1988 (U.S. Fish and Wildlife Service, 1978, 1988). These plans established objectives and outlined steps for recovery that would provide for viable black-footed ferret populations in captivity and in the wild throughout the historical range. A common element in both plans was locating additional wild populations both for preservation and as a source of genetic diversity for the captive population. Brussard and Gilpin (1989) believed that any ferret still extant in the wild should be captured to augment the gene pool available to the captive breeding program. In addition, a multitude of individuals and organizations began work on delineating the historical range of the black-footed ferret, defining and identifying suitable habitat, and developing methodologies and techniques to find remaining populations. This paper presents an overview and update on efforts to locate an undiscovered population of ferrets.

Techniques for Finding a Wild Population of Ferrets

Methodologies to locate black-footed ferrets were first developed during the 11 years (1964–74) that a South Dakota population was studied (Hillman, 1968a,b; Sheets, 1970; Fortenbery, 1972; Hillman and Linder, 1973). Henderson and others (1969) presented important life history and behavioral characteristics, in addition to techniques for studying and locating black-footed ferrets. Nevertheless, Hillman and Linder (1973) emphasized the need to develop more efficient and conclusive techniques for detecting the presence of ferrets on prairie dog (*Cynomys* spp.) towns.

After the South Dakota population disappeared (the last wild ferrets in South Dakota were trapped in 1973; Carpenter and Hillman, 1978), the U.S. Fish and Wildlife Service's (FWS) Denver Wildlife Research Center (DWRC), Section of Wildlife Ecology on Public Lands, conducted black-footed ferret surveys on Federal lands (Martin and Schroeder, 1979, 1980; Smith and others, 1982; Martin, 1983). The objectives of those activities were to search for black-footed ferrets and test new or alternative methods for their detection. These methods included searches for sign (i.e., diggings, tracks, bones, scat, plugged burrows) by foot, horseback, snowmobile, and aircraft during daylight hours, as well as searches for ferrets at night using spotlights (on foot and from vehicles). Other techniques involved observing prairie dog behavior, using night vision equipment, and using scent dogs. A partial listing of such searches conducted by DWRC in Wyoming revealed a total of 1,166 person-hours of night searches with spotlights and much more time spent in day searches. Spotlight searches resulted in sightings of 54 coyotes (*Canis latrans*), 168 badgers (*Taxidea taxus*), and 15 long-tailed weasels (*Mustela frenata*), but there were no sightings of ferrets.

In 1981, a new population of black-footed ferrets was discovered near Meeteetse, Wyo. (Schroeder and Martin,

1982). Four years of studies by FWS, Biota Research and Consulting, Inc., and the Wyoming Game and Fish Department increased our knowledge about locating and monitoring black-footed ferrets (Biggins, 1983; Biggins and Fagerstone, 1983; Clark and others, 1984b, 1986, 1988; Anderson and Inkley, 1985; Campbell and others, 1985; Clark, 1985; Richardson and others, 1985, 1987; Biggins and others, 1986; Fagerstone and Biggins, 1986; Johnson and others, 1986; Morkill, 1987). Although Clark and Campbell (1981a) had already devised ferret search guidelines, information from the Meeteetse studies assisted in formulating updated search techniques (Clark and others, 1984a, 1988). It also enabled FWS to develop black-footed ferret survey guidelines for compliance with the Endangered Species Act (ESA) of 1973, as amended (16 U.S.C. 1531–1543) (Schroeder, 1985; U.S. Fish and Wildlife Service, 1986). The Wyoming Cooperative Fish and Wildlife Research Unit, in cooperation with FWS, initiated workshops on black-footed ferret survey techniques in 1987. These workshops demonstrated the most current methodology for finding ferret populations. Training and certification were necessary to promote uniformity in techniques used by consultants and agency personnel. Workshops were held periodically until 1994, when Badlands National Park in South Dakota hosted the final training course. Today, skills to survey for black-footed ferrets are developed by individuals participating in field work at one of the active reintroduction sites in six States and in Mexico.

Guidelines were prepared by FWS to locate at least one animal of a population within three consecutive nights of spotlight surveys in a portion of the habitat. Using these survey guidelines (U.S. Fish and Wildlife Service, 1986), the probability of detecting ferrets was found to be high under simulated field conditions (Lindzey and Marinari, 1992; Marinari, 1992). Unpublished data from spotlight surveys for the reintroduced population of black-footed ferrets studied in the mid-1990s on the UL Bend National Wildlife Refuge in Montana confirmed the effectiveness of spotlight surveys using the FWS protocol (R. Matchett, oral commun., 2003). Spotlight surveys conducted while telemetry crews were monitoring radio-tagged ferrets suggested that over 90 percent of the ferrets above ground (as indicated by telemetry) were observed by search crews. Similarly, analysis of ferret observations over a 10-year period in the same area suggested high detectability of ferrets, given adequate search effort (Biggins, Godbey, Matchett, and others, this volume).

Henderson and others (1969) first proposed the use of a helicopter or airplane to locate ferrets during winter. Martin and Schroeder (1980) tested both fixed-wing aircraft and a helicopter for winter surveys to locate ferret sign. They found helicopters more practical because badger diggings were more easily found from helicopters. Biggins and Engeman (1986) found fixed-wing aircraft acceptable for locating ferret sign in winter. Aerial ferret surveys from helicopters were used effectively to survey the large white-tailed prairie dog (*C. leucurus*) complex in northwest Colorado and northeast Utah (U.S. Fish and Wildlife Service, 1989). Aerial surveys with helicopters or fixed-wing aircraft are currently used at some reintroduction sites and have been used successfully to locate ferrets that have dispersed into outlying prairie dog colonies (R. Matchett, oral commun., 2003).

In 1978, the DWRC began testing the use of scent dogs to locate black-footed ferrets or their sign (Conway and Dean, 1979; Southwest Research Institute, 1979; Martin and Schroeder, 1980). Two dogs were trained with scat obtained from captive black-footed ferrets held at FWS's (now U.S. Geological Survey's) Patuxent Wildlife Research Center in Laurel, Md. These dogs were later tested at Meeteetse, Wyo., in 1981 and demonstrated the ability to identify burrows known to be occupied by ferrets. Matchett and Smith (2001) successfully located reintroduced ferrets in Montana with trained scent dogs. Reindl (2004) proposed further testing and use of scent dogs in locating black-footed ferrets dispersing from reintroduction sites. Although variability of individual scent dog performance remains a problem, these studies indicate that dogs may be a useful supplement to spotlight surveys, particularly at sites where conventional search efficiency is poor. For example, scent dogs will be used during 2005 in remote, hard-to-search areas of the Colorado/Utah black-footed ferret reintroduction site (S. Reindl, oral commun., 2004).

Before the discovery of the Meeteetse population, Clark and Campbell (1983) tested a track station survey method using a variety of lures to detect nocturnal mammalian carnivores. Hammer and Anderson (1985) further studied the usefulness of track stations and numerous attractants to determine whether black-footed ferrets were present. Tracking and camera stations did not record any visitation in areas occupied by ferrets in the Meeteetse habitat. Scent stations were tested in ferret-occupied habitat in South Dakota with similar results (T. Livieri, oral commun., 2005). Scent attractants, track stations, and remote cameras have not been proven effective for locating ferrets in the wild.

Weasel-like scats have been collected during nocturnal and daylight surveys for ferrets and ferret sign (Henderson and others, 1969; Fortenbery, 1972; Martin and Schroeder, 1979; Clark and others, 1984a, 1988; Richardson and others, 1987). Typical black-footed ferret scat has been described, but identification of mustelid scat to species is often problematic. Johnson and others (1986) compared the fecal bile acid characteristics of known black-footed ferret scat and other known small carnivores and concluded that these acids did not enable positive identification of individual ferret scats. They did, however, suggest that ferret scats might be identifiable with reasonable confidence using gas-liquid chromatography, a technique yet to be thoroughly tested. Recent advances in DNA testing may provide a reliable and practical method to identify black-footed ferret scats where other sign is not discernible.

Reintroduced black-footed ferrets afforded renewed opportunities to gain knowledge on ferret behaviors, thereby increasing our ability to detect free-ranging ferrets. The first reintroduction of captive-raised black-footed ferrets at Shirley Basin, Wyo., yielded much information regarding behavior, dispersal, and postrelease survival (U.S. Fish and Wildlife Service, 1992; Wyoming Game and Fish Department, 1992, 1993, 1994, 1995; Oldemeyer and others, 1993). Subsequent reintroductions in South Dakota, Montana, Arizona, Colorado, and Utah have each added new data, which collectively have contributed to validating and refining effective search techniques.

Historical Sighting Reports and Surveys

Anderson and others (1986) provided an exhaustive summary of black-footed ferret specimens from North America, beginning with the first specimen collected by Audubon and Bachman in 1851. One of the earliest efforts to solicit black-footed ferret sightings occurred in 1952 (Cahalane, 1954). During the period 1946–53, 42 black-footed ferrets were reported from 42 localities, mostly in South Dakota, Montana, Nebraska, and Colorado (Cahalane, 1954). About one-third of the animals observed were found dead or were trapped (killed), shot, hit by vehicles, or died in captivity.

Cahalane's (1954) call for a life history study of the black-footed ferret was answered in 1964 with the discovery of the population in Mellette County, S. Dak. Before the South Dakota population disappeared, a black-footed ferret and prairie dog workshop in 1973 brought together State, Federal, and academic interests to present historical and current knowledge on prairie dogs and black-footed ferrets (Linder and Hillman, 1973). Eleven States, Federal agencies, and academic institutions provided information on available habitat, historical and recent black-footed ferret sightings, and efforts to locate additional populations (Clark, 1973; Grondahl, 1973; Henderson and Little, 1973; Lewis, 1973; Lewis and Hassien, 1973; Locke, 1973).

Kansas was one of the first States to have an active "Wanted: Black-footed Ferret" program. Historical ferret sightings, ferret specimen records, and new sighting reports formed the foundation for actively looking for additional populations (Henderson and Little, 1973). Letters and pamphlets were widely disseminated, supported by articles in local newspapers and magazines and by public radio and television announcements (Henderson, 1969). A color "Wanted Alive" poster was later produced and sent to all States within the original range of the black-footed ferret (appendix, fig. A1). Clark (1973, 1978, 1980) and Clark and Campbell (1981b) took a similar approach in Wyoming, identifying habitat and gathering historical and new specimen records and sighting reports. Campbell (1989) described searches to locate black-footed ferret populations conducted in Montana between 1984 and 1989. Crete (1985) discussed FWS's efforts to work with State agencies and private entities to find other wild populations of ferrets. A second major black-footed ferret workshop was held in 1984 in Laramie, Wyo. Federal and State agencies summarized new efforts to handle black-footed ferret sighting reports (Cada, 1985; Grode, 1985; Hammer, 1985; Hasenyager, 1985; Lengkeek, 1985).

Because of funding constraints and the lack of any legal mandate, searches for remaining populations of black-footed ferrets were at times limited. For example, despite the black-footed ferret's inclusion in the first list of rare and endangered wildlife by the U.S. Department of the Interior in 1964 (Clark, 1989), in the 1966 Endangered Species Preservation Act, and in the Endangered Species Conservation Act of 1969, there were no prohibitions of harm to a listed species ("taking" was prohibited only within national wildlife refuges) and therefore no requirements to determine whether black-footed ferrets were present prior to authorizing projects that might harm ferrets or modify their habitat. By 1965, the Department of the Interior had established a policy on precontrol surveys for prairie dog control programs throughout the range of the black-footed ferret on all classes of land (Berryman and Johnson, 1973). This policy was initially for, and first applied to, prairie dog control programs on Pine Ridge Indian Reservation in South Dakota (Hanson, 1988, 1993). New Mexico also initiated precontrol surveys for black-footed ferrets during that time (Hubbard and Schmitt, 1983). The policy on precontrol surveys was further refined by Executive Order 11643 (Berryman and Johnson, 1973). Jobman and Anderson (1985) reviewed other Federal authorities that might affect or be used in locating funds or facilitating ferret recovery activities. Schroeder (1988), however, noted the requirement for ferret surveys that was triggered by the ESA of 1973. Under section 7(a)(2), Federal agencies are required to consult with FWS to ensure that any action they authorize, fund, or carry out is not likely to jeopardize the continued existence of any endangered or threatened species or result in the destruction or adverse modification of a species' designated critical habitat. If suitable habitat (i.e., capable of supporting at least one black-footed ferret) is present within the action area, FWS has the authority to recommend that a ferret survey precede the project. In 1986, to provide some consistency in survey recommendations, FWS developed standard survey guidelines (Schroeder, 1985; U.S. Fish and Wildlife Service, 1986). When properly implemented, the prescribed strategy has good potential to detect a population of black-footed ferrets. Validating whether suitable habitat is occupied by ferrets is necessary to determine if an action may adversely affect the species. Because of the policy to include precontrol surveys for black-footed ferrets after 1965, the mandatory consultation requirements for Federal agencies in the ESA of 1973, and pesticide registration label statements (U.S. Environmental Protection Agency, 1987), surveys for black-footed ferrets by Federal agencies and their consultants have been occurring for 40 years. Black-footed ferret populations could have escaped detection because some surveys were inadequate or because some suitable habitats were never surveyed. Nonetheless, these surveys have covered large areas without finding a population of living ferrets (but they have resulted in discovery of old black-footed ferret remains).

In the initial black-footed ferret recovery plan (U.S. Fish and Wildlife Service, 1978), one recovery task was to map the amount of prairie dog habitat occupied by black-footed ferrets, to be accomplished by compiling sighting reports for each State within the historical range (Jobman and Anderson, 1981a). The FWS's Pierre, S. Dak., office was designated as the receiving station for all black-footed ferret sightings; this responsibility was moved to Grand Island, Nebr., in 1985. A questionnaire and letter requesting ferret sightings between January 1, 1970, and January 1, 1981, were sent to Provincial (Canadian), Federal, State, and private (tribal, industry, conservation, and recreation groups) institutions (Jobman and Anderson, 1981b), resulting in reports of 228 sightings. Sightings were classified as confirmed, probable, or unconfirmed. Periodic updates (W. Jobman, written commun., 1987–92) to the original report added the following additional sightings: 232 (1987), 51 (1988), 25 (1989), 26 (1990), 31 (1991), and 25 (1992). Partly because of the paucity of additional sightings, updates were discontinued in 1992, and sighting records are no longer formally maintained by FWS. Individual State or FWS offices may maintain records, however.

There are six reintroduced populations of black-footed ferrets that are designated nonessential, experimental in accordance with section 10(j) of the ESA. The black-footed ferret reintroduction sites represented the best habitat available and would seem to have been likely places to find any extant ferret populations. To comply with Section 10(j), all of these release sites were surveyed for resident black-footed ferrets. For example, there were 350 black-footed ferret surveys conducted on lands occupied by prairie dogs at the first site designated (Shirley Basin/Medicine Bow, Wyo.) to receive black-footed ferrets in 1991 (U.S. Fish and Wildlife Service, 1991). Other areas designated as nonessential, experimental populations received similar search efforts (U.S. Fish and Wildlife Service, 1993, 1994, 1996, 1998). Resident populations of ferrets were not found in any of the six areas.

Early Reward Programs

Throughout the 1970s, many States within the historical range of the black-footed ferret solicited sightings of ferrets. In 1974, Dr. Tim Clark, through an effort funded by the National Geographic Society and the National Academy of Sciences, solicited sightings from Wyoming and all States within the historical range of the black-footed ferret (Campbell, 1989). Clark went a step further by offering a $50 reward for a photograph or other information leading to the discovery of ferrets in the wild. "Wanted" posters (appendix, fig. A2) were widely distributed, and the reward was increased to $250 in 1980.

Other States, such as Oklahoma (Hassien, 1976) and New Mexico (Hubbard and Schmitt, 1983), had active publicity programs to solicit sighting reports of black-footed ferrets. The New Mexico Department of Game and Fish during 1978–81 and the New Mexico State Office of the Bureau of Land Management in 1982 conducted well-organized campaigns to solicit black-footed ferret sightings (Hubbard and Schmitt, 1983). The program was well publicized through posters, postcards, newspapers, magazines, and television. None of the 78 records produced was considered reliable evidence for the continued existence of black-footed ferrets in New Mexico (Hubbard and Schmitt, 1983).

Clark's $250 reward was paid to the finders of the Meeteetse, Wyo., ferret that led to the discovery of the last known extant population. Following that seminal event, biologists developed a program to locate ferrets in Montana by offering a monetary reward (Campbell, 1989). In 1983, Montana Fish, Wildlife and Parks and Biota Research and Consulting, Inc., developed a reporting system designed to standardize and assess ferret sightings, presenting criteria to evaluate each sighting and a protocol to follow if ferrets were discovered. The publicity resulted in 69 ferret reports by August 1986, but none resulted in locating and capturing a live black-footed ferret. In August 1986, Montana Fish, Wildlife and Parks initiated a new program soliciting ferret sightings but now offering a monetary reward (Flath, 1987). It included a mailer (appendix, fig. A3) describing the reward program and a standardized reporting form (appendix, fig. A3). A $5,000 reward for information leading to the discovery of a wild population of black-footed ferrets in Montana was offered by Wildlife Conservation International (a subsidiary of the New York Zoological Society). This program not only offered a significant reward but also made it the responsibility of the person submitting the sighting to include adequate information, limiting the need for follow-up on reports that were questionable. The reward program was aggressively advertised and included the distribution of "Wanted" posters (appendix, fig. A4) in post offices, public buildings, and businesses. The monetary reward program generated 66 additional responses (Campbell, 1989), but none led to the discovery of additional ferrets.

Recovery Activities at the National Ecology Research Center

In 1988, FWS approved a revised black-footed ferret recovery plan (U.S. Fish and Wildlife Service, 1988). The FWS's National Ecology Research Center (NERC; now the U.S. Geological Survey's Fort Collins Science Center) was responsible for completion of many of the revised recovery tasks outlined in the plan. One of these tasks was finding additional ferrets to bolster the depauperate genetic representation of ferrets in the captive breeding program. Biggins and Crete (1989), Hanebury and Biggins (1989), and Godbey and Biggins (1994) discussed FWS activities associated with finding ferrets under the new Black-footed Ferret Recovery

Plan. To locate additional ferrets, NERC expanded Montana's black-footed ferret reward program to other States and renewed black-footed ferret surveys on the best remaining ferret habitat.

National Reward Program

The Black-footed Ferret Interstate Coordinating Committee (ICC) was established in 1987 to improve communication and promote ferret recovery in 12 States, two Canadian Provinces, and the State of Chihuahua, Mexico. In 1987, the ICC identified the need for a national reward program and recommended a program similar to that used by Montana. In the fall of 1987, Wildlife Conservation International agreed to apply its $5,000 reward to any State within the former range of the black-footed ferret that wished to participate. States in the program had to be prepared to follow up on all reported sightings within a reasonable amount of time. Montana, Wyoming, Colorado, South Dakota, Utah, Nebraska, Oklahoma, Texas, and Arizona participated in the program. The Navajo Nation, encompassing a large area in both New Mexico and Arizona, also joined the effort. A new poster applicable to all States offering the $5,000 reward was prepared, and by February 1988, 10,000 copies were distributed. The revised posters (appendix, fig. A5) included a photo of a distinctive ferret-digging on snow and sketches of ferret tracks; to qualify for the reward, the observer needed to submit a photograph or information that resulted in verification of one or more live black-footed ferrets. To increase the quality and quantity of responses, Wildlife Conservation International agreed to increase the reward to $10,000 (appendix, fig. A6), effective March 3, 1989. Thousands of updated $10,000 reward posters were mailed to participating States.

New black-footed ferret sighting report forms were developed, incorporating the knowledge gathered from studying the Meeteetse population and experience gained from earlier ferret surveys in response to sighting reports. Ranking criteria and instructions were also developed. A sighting report was scored as highly probable, likely, fair, or unlikely. Such a classification was intended to limit follow-up investigations to the most probable sightings. This conservative approach addressed concerns about "probable" and "confirmed" sighting classifications used by Jobman and Anderson (1981a,b). They defined a probable sighting as one made by a qualified observer or a competent observer who was not positive about a sighting. A confirmed sighting was defined as one made by a competent and dependable observer who had no doubts that the animal seen was a black-footed ferret observed in or near suitable habitat (Jobman and Anderson, 1981a,b).

As part of the national reward program, an extensive effort was made to advertise the reward through all forms of local, statewide, and national media. The communications division of the Wyoming Game and Fish Department assisted NERC in producing audio and video public service announcements on the reward offer, which were sent to radio and television stations. Press releases describing summer and winter ferret behavior and sign, along with the posters, were distributed to the print media. Articles on the black-footed ferret reward program appeared in local and major newspapers and magazines. Major networks ran segments on programs such as *Missing: Reward* and NBC's *Today Show*, and special presentations such as the British Broadcasting Corporation's "Wildlife On One: Wanted Alive," which aired on *National Geographic Explorer*.

Responses to the reward program are difficult to quantify because each State handled incoming reports independently. Reports came directly to NERC or were forwarded from the receiving States. Although respondents provided descriptive photographs, drawings, and detailed characteristics, the photographs typically were of domestic ferrets (*Mustela putorius furo*) from both within and outside the black-footed ferret's historical range (e.g., California, Colorado, Florida, Kentucky, Nevada, Texas, and Utah), as well as photographs of long-tailed and bridled weasels (*Mustela frenata*), badgers, and prairie dogs. Photographs of black-footed ferrets were received from individuals in South Dakota and Alberta, Canada. Both of the photographs matched older photos taken by others, and both reports were judged to be hoaxes. The $10,000 reward offer was terminated on December 31, 1990.

Renewed Search Efforts

During the time of the national reward program, NERC formed black-footed ferret survey teams that were prepared to respond to valid sighting reports and to make one final effort to look for ferrets in suitable habitat. Between 1984 and 1988, six black-footed ferret sightings were reported in or around Waterton Lakes National Park in Alberta, Canada (Laing, 1988). Those reports were investigated in 1989 by Waterton Lakes National Park personnel, a local naturalist, NERC, and FWS personnel (Hanebury, 1989; Harvie, 1989; McGill, 1989). To lend credence to the reports, there were previous specimens or sighting records from Alberta and Saskatchewan (Russell, 1985; Anderson and others, 1986; Laing, 1987; Laing and Holroyd, 1989). In Canada, black-footed ferret surveys before this new effort were limited to those by Millson (1976), Laing (1987), and Laing and Holroyd (1989). Laing and Holroyd (1989) listed 15 recent sightings from 1967 to 1986 and surveyed all reported sites. No black-footed ferrets were confirmed by either the past efforts or the more recent efforts by NERC in and around Waterton Lakes National Park. Highly ranked reports on Navajo Nation lands in New Mexico were also investigated with negative results (Hanebury, 1988a). A brief search (26 person-hours) in the largest black-tailed prairie dog complex in North America, in Chihuahua, Mexico (Ceballos and others, 1993), did not detect any black-footed ferrets (Hanebury, 1988b), but there were 33 sightings of coyotes and 4 sightings of badgers. A partial tally of accessible data revealed 978 person-hours of spotlight searches conducted by NERC personnel in response to range-wide ferret sighting reports. The searches resulted in sightings of many other predators, including 187 coyotes, 193 badgers, and 17 long-tailed weasels, but the widely advertised $10,000 reward and subsequent investigations produced no proof of free-ranging ferrets.

In addition to responding to the sighting reports, NERC survey crews directed efforts to the locations that seemed most likely to harbor ferrets as determined by specimen records, clustered sighting reports, and information suggesting the presence of high-quality habitat (Jobman and Anderson, 1981b; Anderson and others, 1986; W. Jobman, written commun., 1984, 1992). These areas were located in South Dakota, Montana, and Wyoming. In the mid-1970s, when no remaining South Dakota ferret populations could be found, searches throughout the historical range of the black-footed ferret were undertaken by State resource agencies, private consultants, industry, university students, private citizens, and Federal agency biologists. Because no centralized repository for black-footed ferret survey data existed, it is impossible to quantify the hours devoted to spotlighting for ferrets, the area covered, or how many times the same area was searched through time.

Other evidence of a declining black-footed ferret population includes the number of ferret specimens obtained from poisoning, trapping, vehicle collisions, or other sources. Peak numbers occurred during the 1920s and 1930s (fig. 1), perhaps the period when the largest areas of prairie dog colonies were poisoned. Biggins and Schroeder (1988) speculated that this increase probably reflected increased attention given the species rather than a change in the population. No specimens were retrieved during the late 1970s and early 1980s. Although trapping probably decreased during that time, vehicular traffic and miles of roads increased. Cahalane (1954) reported that out of 42 sighting records from the period 1946–53, 17 ferrets were killed before or after the sighting. Four of those deaths were road kills between 1948 and 1953. During studies of the ferret population in south-central South Dakota in Mellette County, eight road-killed ferrets were documented in about 8 years (Hillman and Linder, 1973). There were no reported ferret road kills during the decade of the 1980s. It was not until 1994, after captive-bred black-footed ferrets were reintroduced to unoccupied habitat, that ferret specimens again began to be collected as road kills (fig. 1).

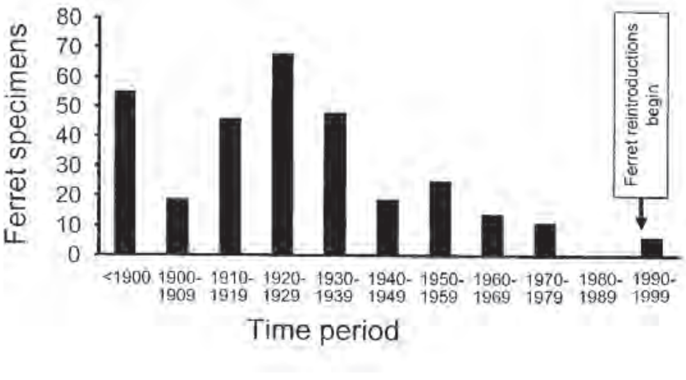

Figure 1. Number of black-footed ferret (*Mustela nigripes*) specimens collected by decade from Anderson and others (1986) and Clark (1989), including the decade after ferret reintroductions.

Summary

Since the decline of the last known ferret population in South Dakota, substantial effort has been devoted to identifying viable ferret habitat and locating any remaining isolated ferret populations. Survey techniques were developed and used as a reliable standard to find black-footed ferrets. Search efforts increased after the establishment of a policy for prairie dog precontrol surveys in 1965 and following implementation of the ESA in FWS field offices throughout the historical range of the ferret. None of the searches performed to implement recovery plan tasks, to comply with ESA section 7 consultation requirements (including pesticide registration), and to ensure compliance with the “take” prohibitions of section 9 of the ESA, nor heroic efforts by private individuals and conservation groups, have found any black-footed ferrets in the wild. At some locations, the lack of success in finding wild ferrets, combined with the desire by some agencies and organizations to expedite projects (e.g., prairie dog control, oil and gas development) in ferret habitat (i.e., prairie dog colonies), has resulted in requests for FWS to declare areas entirely “ferret free” (i.e., to “block-clear” the area from the need for preproject ferret searches) (Campbell and others, 1990). Today, requirements for preproject ferret surveys have been either officially eliminated or deemphasized in all of the 12 States composing the historical range of the black-footed ferret. The majority of the ferret range in South Dakota has been either block-cleared or exempted from the need for ferret surveys because of designation of experimental areas for ferret reintroduction through deliberative processes (South Dakota Department of Agriculture and South Dakota Department of Game, Fish and Parks, 2003). Other States with significant remaining areas of viable ferret habitat (active prairie dog colonies) have officially block-cleared habitat not considered valuable for ferret recovery (Colorado, R. Krueger, oral commun., 2005; Wyoming, M. Jennings, written commun., 2004). For the most part, North Dakota (B. Bicknell, oral commun., 2005), Nebraska (B. Harms, oral commun., 2005), Kansas (D. Mulhern, oral commun., 2005), Oklahoma (S. Harmon, oral commun., 2005), Utah (R. Chi, oral commun., 2005), and Texas (J. Hughs, oral commun., 2005) do not require preproject ferret surveys for section 7 consultation. New Mexico considers the black-footed ferret to be extirpated and therefore does not require preproject surveys (M. Murphy, oral commun., 2005).

Some organizations have promoted block-clearing as a strategy to improve public sentiment toward black-footed ferret recovery and prairie dog conservation (Patton and

Leachman, 1991). Further, the now widely held view that the probability of ferrets persisting in the wild is low, combined with the expense of conducting guideline-standard ferret searches, has caused FWS to relax section 7 consultation requirements (M. Lockhart, written commun., 2003) and propose that tasks relating to additional ferret searches be deemphasized in a second revision of the black-footed ferret recovery plan (U.S. Fish and Wildlife Service, 2004). A review of ferret survey needs is still in progress, however, and will be reflected in the final revised recovery plan.

Over 15 years ago, Lacy and Clark (1989) examined genetic variability in black-footed ferret populations and stated that it was unlikely that a long-term viable population of ferrets existed in the wild. We believe that the probability of finding ferrets that stem from noncaptive stock is already small and diminishes with each passing year. There are, however, several remaining considerations. With the reintroduction of over 1,900 captive-raised black-footed ferrets and with much recruitment of wild-born kits since 1991, the possibility of newly established populations in the wild will increase. The example of the remarkable persistence of ferrets in the disease-prone, vast, but fragmented habitat of Shirley Basin, Wyo. (Grenier and others, 2004), gives us hope that free-ranging ferrets will persist in other States as reintroductions continue. In addition to the need to monitor reestablished ferret populations, there will be a continued need for improved monitoring methodologies and searches to locate future populations established by dispersing young.

Appendix. Posters Used To Solicit Reports of Black-footed Ferret Sightings

WANTED ALIVE

Black Footed Ferrets

and Their Location

Photo—F. Robert Henderson

Size: About 2 feet long including the tail.
Identifying Markings: Black face-mask, black-tipped tail, black feet, body color is yellow-tan.
Habitat: Usually prairie dog towns or near them. May be seen elsewhere when moving between prairie dog towns, during searches for food and during breeding season.
Abundance: One of rarest mammals in North America.

PLEASE, report! (See contact at bottom of poster)

DON'T BE CONFUSED BY THESE ANIMALS THAT LOOK LIKE THE BLACK-FOOTED FERRET

Photo—F. Robert Henderson

European Ferret

Size: About the same as the black-footed ferret.
Identifying Markings: Similar to those of the black-footed ferret, **except,** nose more pointed, more black on tail and the fur is more bushy to give a heavier body appearance. Body color usually appears darker, because of dark-colored guard hairs. Feet **are** black.
Habitat and Abundance: Common laboratory animal and sold in pet shops. Often released to the wild by owners.

Photo—Jon Farrar

Long-Tailed Weasel

Size: About one-half the size of a black-footed ferret.
Identifying Markings: Yellowish-white underparts and black-tipped tail. Body color is reddish-brown. Winter color is white except black-tipped tail. Feet **not** black.
Habitat and Abundance: Can be found on most land habitats where prey species available, and often near water.

Bridled Weasel

Size: About one-half the size of a black-footed ferret.
Identifying Markings: Same as long-tailed weasel only has black face-mask. Feet **not** black.
Habitat and Abundance: Similar to long-tailed weasel. Mostly occurs in Southwestern U.S.

$50 REWARD

for Photograph & Information

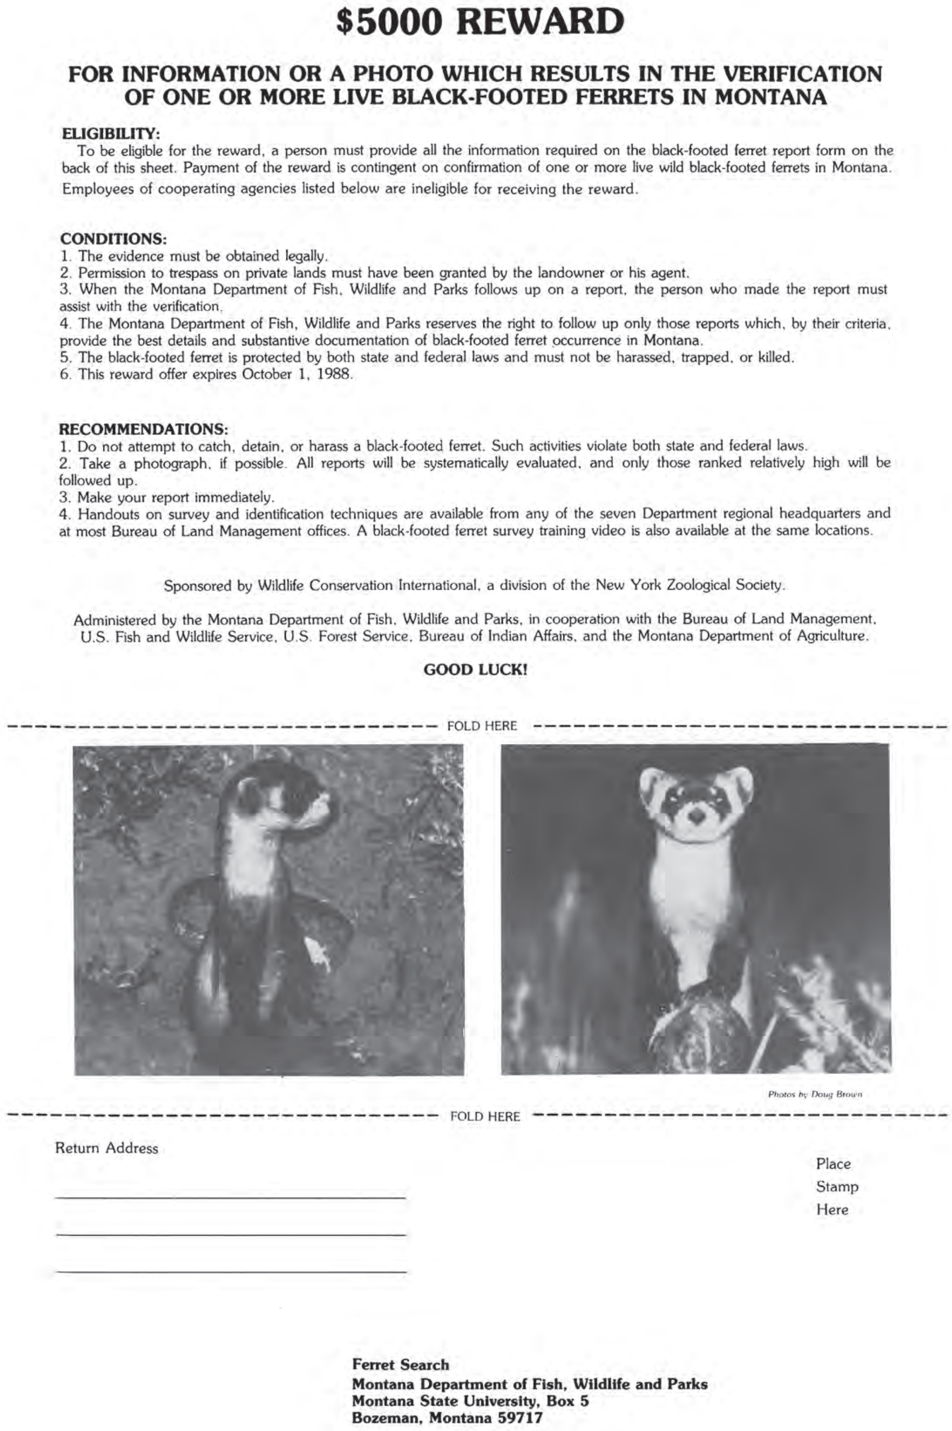
REWARD CONDITIONS: The ferret is an endangered species and is protected by very stringent federal and state laws. The reward WILL NOT be paid for any ferret caught in traps or killed by the finder. The reward will be given to the FIRST person providing information leading to the discovery and verification of the existence of black-footed ferrets (Mustela nigripes) in Wyoming. Skins and skeletons of ferrets struck accidently by cars and found along roads, reports of ferrets seen or photographs taken in an area where a representative of the "Ferret Search" project subsequently observes a ferret will qualify for the reward. A few ferrets have been seen in most parts of Wyoming in recent years. Ferrets eat prairie dogs and are usually found on or near prairie dog towns.

IDENTIFYING CHARACTERISTICS: The ferret is the size of a medium sized mink, about 18 inches long and 2.5 pounds. Unique features are black face mask and black feet. Do not confuse it with long-tailed weasels (no mask or black feet).

CONTACT: Tim W. Clark, Ferret Search, Box 1330, Jackson, Wyoming 83001; Telephone: 307-733-4806 as soon as possible after the sighting.

"Ferret Search" supported by National Geographic Society and The National Academy of Sciences. Reward offer expires 1 November, 1975.

Figure A2. A 1974 poster distributed by Tim Clark, offering a $50 reward for information leading to discovery of black-footed ferrets (*Mustela nigripes*).



$5000 REWARD

FOR INFORMATION OR A PHOTO WHICH RESULTS IN THE VERIFICATION OF ONE OR MORE LIVE BLACK-FOOTED FERRETS IN MONTANA

ELIGIBILITY:

To be eligible for the reward, a person must provide all the information required on the black-footed ferret report form on the back of this sheet. Payment of the reward is contingent on confirmation of one or more live wild black-footed ferrets in Montana. Employees of cooperating agencies listed below are ineligible for receiving the reward.

CONDITIONS:

1. The evidence must be obtained legally.
2. Permission to trespass on private lands must have been granted by the landowner or his agent.
3. When the Montana Department of Fish, Wildlife and Parks follows up on a report, the person who made the report must assist with the verification.
4. The Montana Department of Fish, Wildlife and Parks reserves the right to follow up only those reports which, by their criteria, provide the best details and substantive documentation of black-footed ferret occurrence in Montana.
5. The black-footed ferret is protected by both state and federal laws and must not be harassed, trapped, or killed.
6. This reward offer expires October 1, 1988.

RECOMMENDATIONS:

1. Do not attempt to catch, detain, or harass a black-footed ferret. Such activities violate both state and federal laws.
2. Take a photograph, if possible. All reports will be systematically evaluated, and only those ranked relatively high will be followed up.
3. Make your report immediately.
4. Handouts on survey and identification techniques are available from any of the seven Department regional headquarters and at most Bureau of Land Management offices. A black-footed ferret survey training video is also available at the same locations.

Sponsored by Wildlife Conservation International, a division of the New York Zoological Society.

Administered by the Montana Department of Fish, Wildlife and Parks, in cooperation with the Bureau of Land Management, U.S. Fish and Wildlife Service, U.S. Forest Service, Bureau of Indian Affairs, and the Montana Department of Agriculture.

GOOD LUCK!

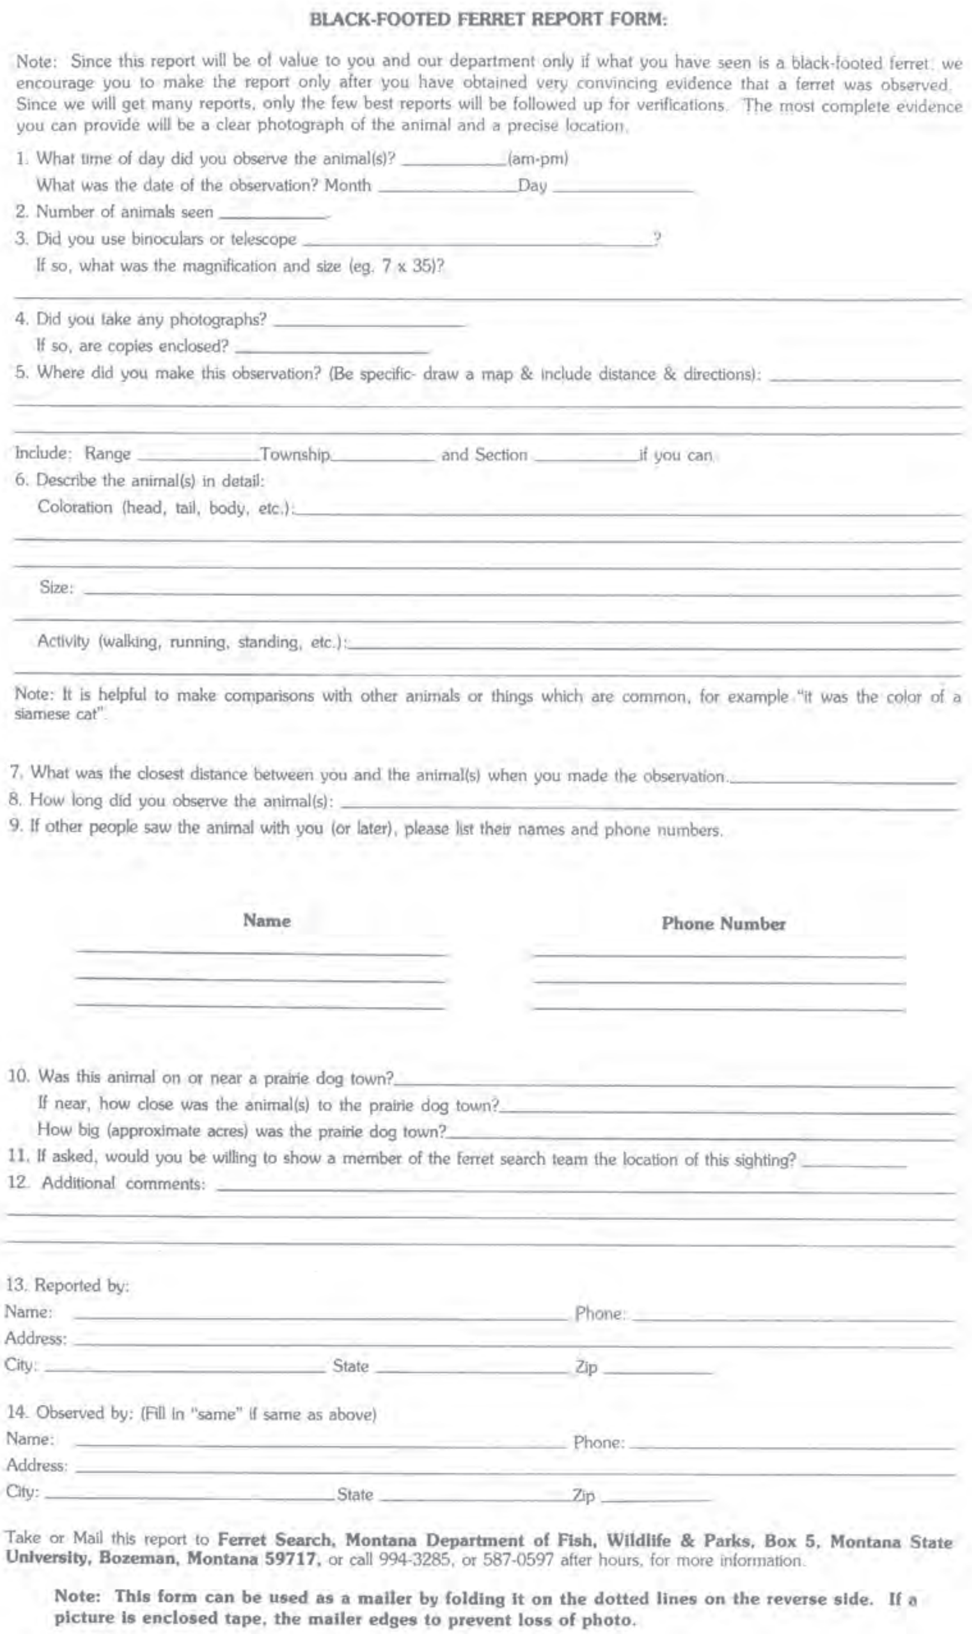
Figure A3. A pamphlet and report form, distributed in Montana starting in 1983, advertising a $5,000 reward for a verified black-footed ferret (*Mustela nigripes*) sighting.



BLACK-FOOTED FERRET REPORT FORM:

Note: Since this report will be of value to you and our department only if what you have seen is a black-footed ferret, we encourage you to make the report only after you have obtained very convincing evidence that a ferret was observed. Since we will get many reports, only the few best reports will be followed up for verifications. The most complete evidence you can provide will be a clear photograph of the animal and a precise location.

1. What time of day did you observe the animal(s)? ________(am-pm)
What was the date of the observation? Month ________Day ________
2. Number of animals seen ________.
3. Did you use binoculars or telescope ________?
If so, what was the magnification and size (eg. 7 x 35)?
____
4. Did you take any photographs? ________
If so, are copies enclosed? ________
5. Where did you make this observation? (Be specific- draw a map & include distance & directions): ________
____
____
Include: Range ________Township________ and Section ________if you can.
6. Describe the animal(s) in detail:
Coloration (head, tail, body, etc.):________
____
____
Size: ________
____
Activity (walking, running, standing, etc.):________
____

Note: It is helpful to make comparisons with other animals or things which are common, for example "it was the color of a siamese cat".

7. What was the closest distance between you and the animal(s) when you made the observation.________
8. How long did you observe the animal(s): ________
9. If other people saw the animal with you (or later), please list their names and phone numbers.

Name	**Phone Number**

10. Was this animal on or near a prairie dog town?________
If near, how close was the animal(s) to the prairie dog town?________
How big (approximate acres) was the prairie dog town?________
11. If asked, would you be willing to show a member of the ferret search team the location of this sighting? ________
12. Additional comments: ________
____
____

13. Reported by:
Name: ________ Phone: ________
Address: ________
City: ________ State ________ Zip ________

14. Observed by: (Fill in "same" if same as above)
Name: ________ Phone: ________
Address: ________
City: ________State ________Zip ________

Take or Mail this report to **Ferret Search, Montana Department of Fish, Wildlife & Parks, Box 5, Montana State University, Bozeman, Montana 59717,** or call 994-3285, or 587-0597 after hours, for more information.

Note: This form can be used as a mailer by folding it on the dotted lines on the reverse side. If a picture is enclosed tape, the mailer edges to prevent loss of photo.

Montana Department of Agriculture

REWARD CONDITIONS

The black-footed ferret is an endangered species protected by very stringent federal and state laws. The reward WILL NOT be paid for any black-footed ferret intentionally harassed, trapped, or killed by the finder. The reward will be paid to the person who provides information leading to the discovery and verification of the existence of the first live black-footed ferret in Montana. Examples of information to supply include: (1) skins and skeletons of black-footed ferrets struck accidentally by cars and found along roads, (2) observations of black-footed ferrets reported on standard forms available from any district office of the Montana Department of Fish, Wildlife and Parks, or (3) photographs.

The reward will not be paid to someone who was on private lands illegally.

The reward is limited to Montana and will expire on October 1, 1988. In the event of a tie or a question concerning the awarding of the reward, the Montana Department of Fish, Wildlife and Parks will be the final judge. The Department may elect to have the reward shared by two or more individuals if warranted. The final burden of proof will be the responsibility of the person(s) making the report, including assisting with the verification.

INELIGIBILITY: Employees of the Montana Department of Fish, Wildlife and Parks and cooperators are ineligible for the reward.

WANTED ALIVE

Black-footed ferrets and their locations

CHARACTERISTICS
The black-footed ferret *(Mustela nigripes)*, a nocturnal predator, is the size of a medium-sized mink, about 18 inches long and 2½ pounds. **Unique features are a black face mask and black legs.** Do not confuse it with a long-tailed weasel, a smaller animal without black legs. The domestic ferret sold in pet stores is not a black-footed ferret. The black-footed ferret is usually found in or near prairie dog towns.

DIGGINGS
Diggings can be evidence of ferret presence if they are found in winter and prairie dogs have been inactive. Black-footed ferret diggings are deposits of loose soil pulled from prairie dog size burrows (about 4-inches wide) and left on the surface of the ground or snow (see photograph). A digging should be reported if:

(1) it is deposited on snow and is accompanied by "twin print" type tracks (see illustration in margins)

OR

(2) it is deposited on the ground, is more than 3 feet long, is less than 12 inches wide, and has a trough or furrow-like depression centered along its length.

REWARD CONDITIONS
The black-footed ferret is an endangered species protected by very stringent federal and state laws. The reward WILL NOT be paid for any black-footed ferret intentionally harassed, trapped, or killed by the finder. The reward will be paid to the first person who provides information leading to the discovery and verification of the first live black-footed ferret in each state. Examples of information to supply include: (1) skins and skeletons of black-footed ferrets struck accidentally by cars and found along roads, (2) photographs of ferrets or ferret diggings, or (3) observations of black-footed ferrets or ferret diggings.

The reward will not be paid to someone who was on private lands illegally.

The reward offer is limited to participating states. In the event of a tie or a question concerning the awarding of the reward, the U.S. Fish and Wildlife Service will be the final judge. The Service may elect to have the reward shared by two or more individuals if warranted. The final burden of proof, including assisting with the verification, will be the responsibility of the person making the report. The reward offer is valid from September 1, 1987 through September 31, 1989.

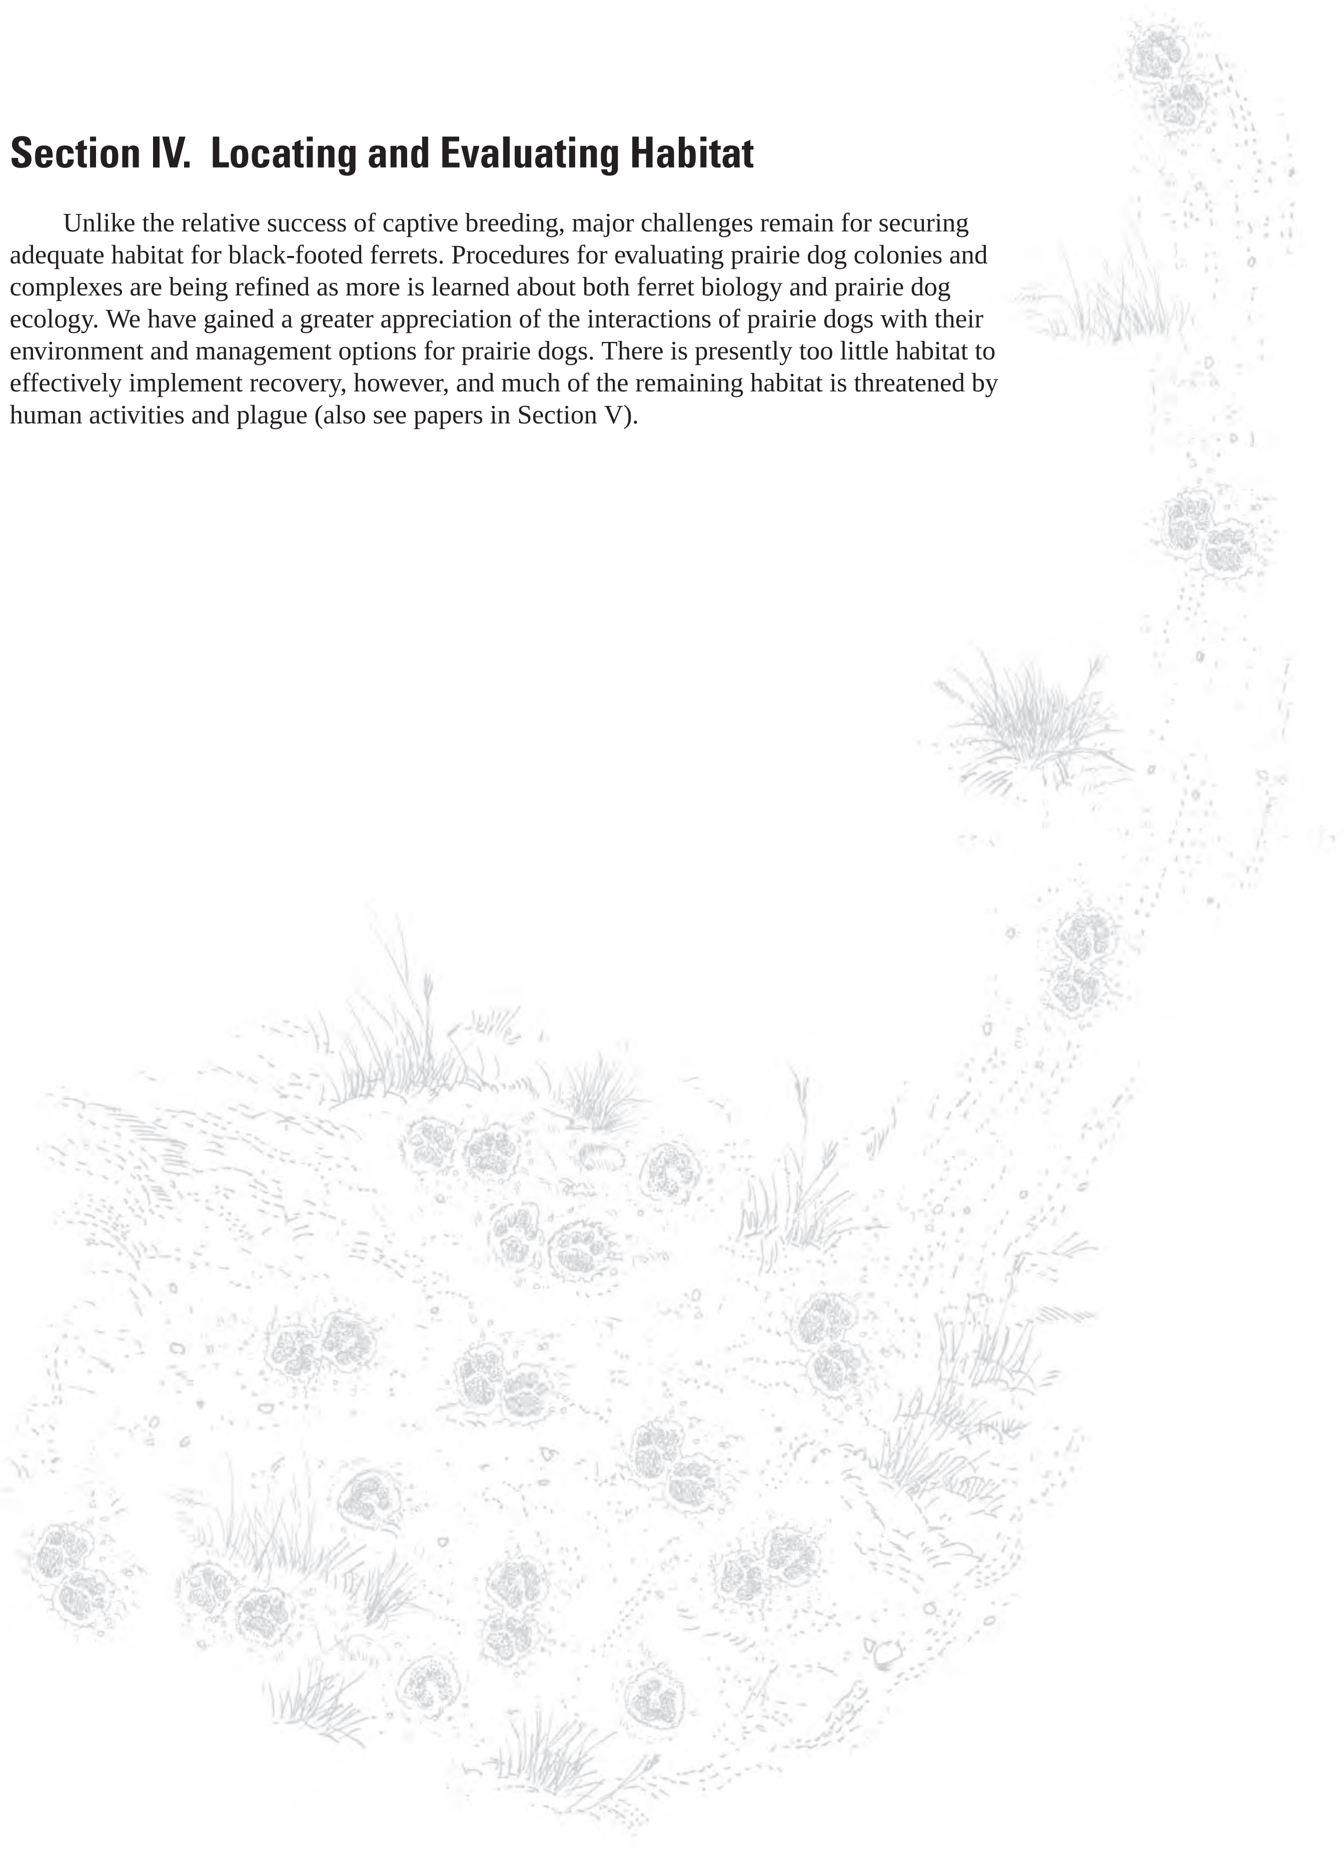
Section IV. Locating and Evaluating Habitat

Unlike the relative success of captive breeding, major challenges remain for securing adequate habitat for black-footed ferrets. Procedures for evaluating prairie dog colonies and complexes are being refined as more is learned about both ferret biology and prairie dog ecology. We have gained a greater appreciation of the interactions of prairie dogs with their environment and management options for prairie dogs. There is presently too little habitat to effectively implement recovery, however, and much of the remaining habitat is threatened by human activities and plague (also see papers in Section V).



Areas Where Habitat Characteristics Could Be Evaluated To Identify Potential Black-footed Ferret Reintroduction Sites and Develop Conservation Partnerships

By Robert J. Luce[1]

Abstract

This paper is an attempt to develop a new, broad list of potential black-footed ferret (*Mustela nigripes*) reintroduction sites across its historical range. I reviewed reports and publications that identified active, inactive, and potential reintroduction sites, including unpublished reports generated by State wildlife agencies and universities. I contacted local experts and reviewed the published and unpublished literature describing colony locations of three species of prairie dogs (*Cynomys* spp.). I list active reintroduction sites and others already planned and identify 70 other sites in the historical range of the black-footed ferret that might meet the biological and habitat suitability requirements for reintroduction of the species within 3–10 years, contingent upon directed management emphasis, State and Federal agency management priority, and, if on private land, landowner concurrence through agreements or incentives. I present this conceptual effort in the hope that identification of sites at this level will prompt discussion, revisions, additions, and deletions and will result in the formation of conservation partnerships that will contribute to black-footed ferret recovery.

Keywords: black-footed ferret, conservation, *Cynomys*, endangered species, *Mustela nigripes*, prairie dog, reintroduction

Introduction

Although many known, large prairie dog (*Cynomys* spp.) complexes have previously been identified, I believe that this paper is the first serious attempt to develop a new, broader list of potential reintroduction sites across the historical range of the black-footed ferret (*Mustela nigripes*). Some of these sites have been considered before, but many have not, or at least not in the same context as in the current effort. I present this conceptual effort in the hope that identification of the sites at this level will prompt discussion, revisions, additions, and deletions, and result in the formation of conservation partnerships that will contribute to black-footed ferret recovery.

Past efforts to identify sites have been constrained by the need to immediately take into account land ownership, plague history, and other factors that do not constrain the current conceptual effort. I hope that this paper prompts many who have not considered contributing to black-footed ferret recovery to get involved with a site in their locality. Several States that have not been involved in black-footed ferret recovery in the past have not previously participated in site identification.

I recognize that there are issues other than ecological ones that must be addressed when identifying potential reintroduction sites; however, I believe that recovery of the black-footed ferret depends first and foremost upon identifying and conserving areas that meet or have the potential to meet the biological parameters for establishment and long-term survival of viable populations. I believe that social and economic issues, including private land rights, economic concerns related to forage competition between livestock and prairie dogs, and others, are vitally important. I also believe, however, that a start must be made. Changes in Federal land management priorities, cooperative management planning on Federal lands, and financial incentives or regulatory assurances for private landowners or tribal governments must logically follow after habitat suitability has been established.

Recovery efforts for the endangered black-footed ferret have faced numerous and significant challenges, including extirpation of the species in the wild, development of captive breeding techniques and reintroduction methods, lack of adequate financial resources, and organizational inefficiencies (Forrest and others, 1985; Clark, 1986; U.S. Fish and Wildlife Service, 1988; Miller and others, 1996). Much work has been accomplished, and much remains to be done in these areas and others, but at present I believe that the most fundamental obstacle to meaningful recovery of the black-footed ferret in the wild is the availability of suitable habitat, both in quantity and quality; that is, prairie dog colonies of sufficient size and proximity to other colonies (Chaplin and others, 1996; Lomolino and others, 2002; Luce, 2003). There is a critical need to identify suitable sites and begin management of those sites for reintroduction and recovery. In fact, this may be the ultimate challenge to black-footed ferret recovery because it involves the greatest potential conflict with other land-use interests. Political and social barriers often surpass in difficulty those in the biological arena.

---

[1] P.O. Box 7, Sierra Vista, AZ 85636.

In the late 1980s, spurred by the need to utilize animals produced by captive breeding, biologists identified several potential reintroduction sites. In 1988–89, R. Luce (written commun., 1995) developed a list of 18 potential reintroduction sites in Wyoming by using data from a variety of sources. Conway (1989) evaluated six of those sites and concluded that only two had prairie dog numbers suitable for black-footed ferret reintroduction. Closer examination of other sites in Wyoming, as well as sites in Arizona, Colorado, South Dakota, and Utah, revealed that many were more or less unsuitable at the time of evaluation for various reasons, principally because prairie dogs did not occupy the sites to the extent that earlier evaluations had recorded or assumed (M. Lockhart, written commun., 1999–2003). Ranking of sites suitable for black-footed ferret reintroduction and recovery has emphasized the importance of large complexes of prairie dog colonies and identification of multiple sites. Additionally, it has been assumed that more densely occupied black-tailed prairie dog (*C. ludovicianus*) colonies are preferable to less dense white-tailed (*C. leucurus*) or Gunnison's (*C. gunnisoni*) prairie dog colonies and that a plague-free environment is preferable. New data documenting maintenance and/or growth of both prairie dog and black-footed ferret populations at reintroduction sites on Gunnison's and white-tailed prairie dog complexes where plague is present in Arizona (B. Van Pelt, oral commun., 2004) and Wyoming (M. Grenier, oral commun., 2004) indicate that these assumptions warrant further investigation.

A revision of the current Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988) is underway, so it is important to note that I do not intend to supersede the site selection process that will be a part of the revised plan. The revised plan may include new downlisting and delisting goals for number of black-footed ferrets and number or location of reintroduction sites, but in either case a large number of potential reintroduction sites must be identified. I offer a new baseline list that includes contributions from all portions of the species' historical range, both previously overlooked sites and recently identified sites. I do not attempt to identify long-term black-footed ferret recovery needs for various areas of the species range because a rangewide delisting goal has not been identified and because a related method for apportioning recovery responsibilities among political jurisdictions has not been formalized to date (see Ernst and others, this volume).

The most promising recovery sites already have active reintroduction programs in place. I believe that several new sites with potential for adequate occupied habitat to be present within 3–10 years should be identified for each of the political jurisdictions within the historical range of the black-footed ferret. It is not appropriate to wait for a definitive answer as to the number of black-footed ferrets necessary for delisting or the amount of actual habitat that will be needed. Many more sites must be evaluated than are currently being considered because environmental unknowns, especially plague and drought, affect the viability of individual sites; therefore, longevity cannot be predicted or guaranteed. In addition, political and social attitudes may change, resulting in loss of support for maintaining adequate occupied prairie dog habitat at a given site. I identify a large number of sites so that no one site will be under pressure for rapid development, but yet the presence of the sites on the list will allow agencies to begin planning toward management of those sites, potentially allowing a significant number of them to be available for black-footed ferret reintroduction in 3–10 years.

Methods

I reviewed previous efforts that identified active, inactive, and potential black-footed ferret reintroduction sites, including the U.S. Fish and Wildlife Service (FWS) reintroduction site list (Conway, 1989; M. Lockhart, written commun., 1999–2003; fig. 1). I also reviewed published literature, including Lair and Mecham (1991), Vanderhoof and Robel (1994), Ernst (2001), and Johnson and others (2003). In addition, I reviewed available information regarding other potential sites, including unpublished reports generated by State wildlife agencies

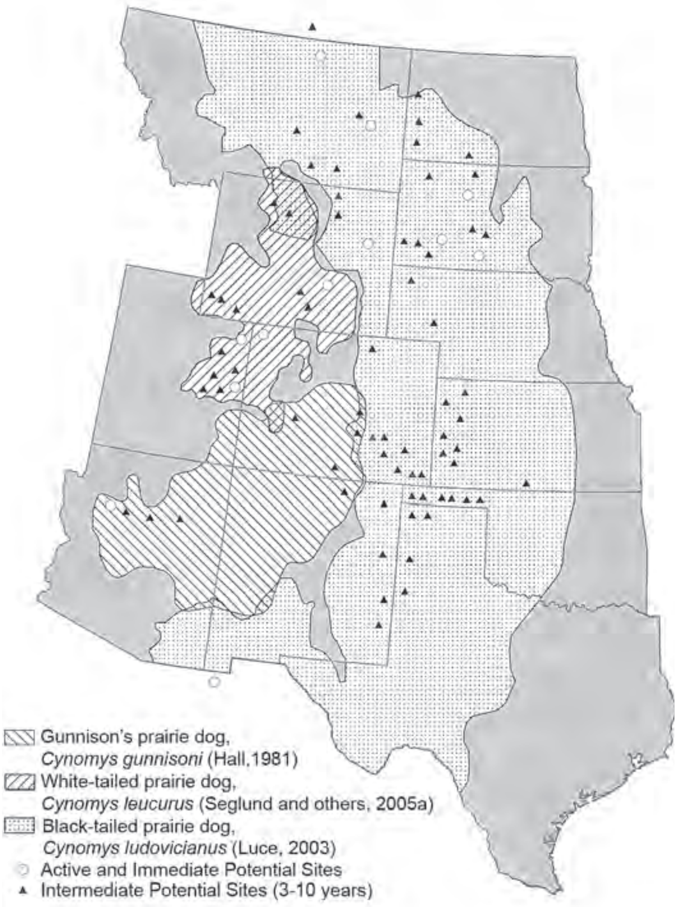


Figure 1. Location of eight active black-footed ferret (*Mustela nigripes*) reintroduction sites (1990–2004); three Immediate Potential Sites (1–3 years); and 70 Intermediate Potential Sites, at which, pending further evaluation, opportunities for reintroducing ferrets may exist in 3–10 years.

and universities, and contacted local experts. I had personal communication with Steve Whiteman, Southern Ute Tribe; Craig Knowles, FaunaWest Wildlife Consultants; Derrick Holdstock and Heather Whitlaw, Texas Parks and Wildlife Department; Julianne Hoagland, Oklahoma Department of Wildlife Conservation; Pamela Schnurr, Colorado Division of Wildlife; Dave Wagner, Northern Arizona University; Bill Woodson, U.S. Army; Mike Albee, U.S. Bureau of Land Management; Tim Byer and Dave Augustine, U.S. Forest Service; Joe Truett, Turner Endangered Species Fund; Allison Puchniak, Montana Department of Fish, Wildlife and Parks; Terry Enk, New Mexico Department of Game and Fish; Pete Gober, Randy Matchett, Scott Larson, John Nysted, and Lou Hanebury, U.S. Fish and Wildlife Service; Mark Lomolino, State University of New York, College of Environmental Science and Forestry; Amy Seglund and Craig McLaughlin, Utah Division of Wildlife Resources; Pat Fargey, Grasslands National Park, Canada; Martin Grenier, Wyoming Game and Fish Department; Tim Vosburgh, Intertribal Black-tailed Prairie Dog Coordinator; Bill Van Pelt, Arizona Game and Fish Department; Rurik List, Instituto de Ecologia, Ciudad Universitaria Coyoacan, Mexico; Travis Livieri, Prairie Wildlife Research; Mike Fritz, Nebraska Game and Parks Commission; and Sandy Hagen, North Dakota Game and Fish Department.

Information was acquired for 12 States within the historical range of the black-footed ferret, five Native American reservations, two States in Mexico, and one Canadian Province. The foundation for this effort was provided by intensive and extensive inventories and preparation of management plans for black-tailed prairie dogs, as summarized in Luce (2003); white-tailed prairie dog survey data, as summarized in Seglund and others (2005a); and Gunnison's prairie dog survey data, as summarized in Seglund and others (2005b).

I use the following terminology. Active Sites are those at which black-footed ferrets have been previously released and are being actively managed. Immediate Potential Sites are those already identified by the Black-footed Ferret Recovery Implementation Team and upon which reintroduction work has begun. Intermediate Potential Sites are those at which opportunities may exist in the 3- to 10-year time frame.

Planning efforts conducted by recovery partners require a queue of potential sites. I provide a locally specific list of all potential black-footed ferret reintroduction sites across the species' historical range but focus on Intermediate Potential Sites since these provide the next step in black-footed ferret reintroduction beyond management of Active Sites. Reintroduction efforts could begin at an Intermediate Potential Site before the minimum occupied habitat identified was available if expansion could be reasonably anticipated within a decade. Therefore, sites that are now below the minimum threshold for occupied habitat are also listed in this paper, anticipating that they have potential to meet or exceed the minimum within 10 years. Although I surmise that long-term potential sites may exist, I do not list those here.

At existing black-footed ferret reintroduction sites, as well as in State black-tailed prairie dog management plans, contiguous habitat is defined as a complex of colonies in which no colony is farther than 7 km from another colony (Biggins and others, 1993). A colony is defined as a concentration of black-tailed prairie dogs with an average density of at least 4.05 individuals/ha (Luce, 2003) or as a concentration of white-tailed prairie dogs with a minimum of 20 burrow openings/ha on 5-ha parcels (Biggins and others, 1993; Seglund and others, 2005a). Colony has not yet been defined for Gunnison's prairie dogs, but the species is biologically similar to the white-tailed prairie dog. Although this rigorous definition was not used to identify the Intermediate Potential Sites in this paper, it must be assumed that sites will be required to meet a similar standard eventually before their full potential for maintenance of a long-term, viable black-footed ferret population can be achieved.

Based on bioenergetic (Biggins and others, 1993) and behavioral considerations (R. Matchett and T. Livieri, oral commun., 2003) and known densities of the respective species, I began with the premise that the minimum adult population of 30 individuals identified in the 1988 recovery plan (U.S. Fish and Wildlife Service, 1988) might require 1,215 ha of contiguous, occupied black-tailed prairie dog habitat; 1,823 ha of contiguous, occupied Gunnison's prairie dog habitat; or 2,430 ha of contiguous, occupied white-tailed prairie dog habitat. I recognize that prairie dog densities vary between sites and at individual sites on an annual basis, but I found it necessary to use averages in this evaluation process.

I also worked from the premise that the amount of extant, occupied habitat noted above may not be necessary to identify potential reintroduction sites and perhaps begin black-footed ferret releases. I suggest that 607.5 ha of contiguous, occupied black-tailed prairie dog habitat; 911.3 ha of contiguous, occupied Gunnison's prairie dog habitat, or 1,215.0 ha of contiguous, occupied white-tailed prairie dog habitat may be sufficient to begin management planning or possible experimental release of black-footed ferrets. The choice of 50 percent was arbitrary and assumes that prairie dog colonies will grow. Of course, many other factors may affect suitability of a reintroduction site, but I believe that these rough measures may allow preliminary identification of a queue of sites that can be further evaluated.

I characterized sites in regard to the species of prairie dog present, the amount of occupied prairie dog habitat, and disease status in a manner similar to that used by M. Lockhart (written commun., 1999–2003). Many of these sites have been recently identified as a result of ongoing inventories of prairie dog habitat.

Results

Current and potential black-footed ferret reintroduction sites are listed below for U.S. States and some Native American tribal lands, Canadian Provinces, and Mexican States having historical prairie dog habitat. Each is preceded by background information related to prairie dog populations. Many sites are in the early stages of identification and mapping; some may not yet be fully mapped, and some have no data on the amount of occupied prairie dog habitat or density of prairie dogs. Sites are summarized in table 1 (Active and Immediate Potential Sites) and table 2 (Intermediate Potential Sites), and locations are illustrated in figure 1.

Arizona

Black-tailed and Gunnison's prairie dogs occurred in Arizona historically. The black-tailed prairie dog was extirpated from Arizona in the 1930s; therefore, reintroduction of black-tailed prairie dogs would be necessary before their colonies could serve as reintroduction sites for black-footed ferrets. In 2002, Wagner and Drickamer (2002) collected data from all potential sources and identified 400 locations with Gunnison's prairie dog colonies. They revisited 293 colonies in 2000 and 2001 and found that 270 were active. Gunnison's prairie dogs are located in northern Arizona from the Colorado River to Flagstaff and eastward along the Little Colorado River. No survey data are available for the Navajo Indian Reservation, which may comprise as much as one-third of the potential range.

Active Sites

Aubrey Valley

Arizona has one active black-footed ferret reintroduction site on a Gunnison's prairie dog complex in Aubrey Valley (Coconino, Yavapai, and Mojave Counties) in the northwestern part of the State (fig. 1). Reintroduction efforts began in 1996. The site is designated a black-footed ferret nonessential experimental population, and releases of captive black-footed ferrets are ongoing. Approximately 25 black-footed ferrets occur in the wild there at present. Total occupied prairie dog habitat is approximately 12,039 ha on a mixture of private, State, and Hualapai Indian Reservation lands. Monitoring at this site has not documented plague during the last 20 years, although it has been noted in the region. Prairie dog populations can be severely affected by drought at this site (M. Lockhart, written commun., 1999–2003).

Intermediate Potential Sites

East of Seligman

Approximately 2,502 ha of active Gunnison's prairie dog colonies were present on-site in 1992. The site is a large open grassland bisected by I-40. Occupied habitat was reduced considerably in 1996 because of a plague epizootic, but recovery began in 2001. This area is <10 km from Aubrey Valley (Wagner and Drickamer, 2002; D. Wagner, oral commun., 2003).

West of Dilkon, Navajo Indian Reservation

The Navajo Natural Heritage Program surveyed Gunnison's prairie dogs in this area to investigate its potential as a black-footed ferret reintroduction site. The survey documented approximately 3,200 ha of occupied habitat. This area was affected by plague in 1996, and there has been little recovery to date (Wagner and Drickamer, 2002; D. Wagner, oral commun., 2003).

Table 1. Sites at which black-footed ferrets (*Mustela nigripes*) have been reintroduced and are being managed (Active Sites), and sites identified by the Black-footed Ferret Recovery Implementation Team where some work preparatory to reintroduction has been done (Immediate Potential Sites).

State	Site name	Nearest town	Plague status
Active Sites			
Arizona	Aubrey Valley	Seligman	Not present
Colorado	Colorado/Utah	Dinosaur	Present
Montana	North-central Phillips County	Malta	Present
South Dakota	Cheyenne River Indian Reservation		
	Conata Basin/Badlands National Park	Wall	Not present
	Rosebud Indian Reservation	Winner	Not present
Utah	Colorado/Utah	Dinosaur, Colo.	Present
Wyoming	Shirley Basin	Medicine Bow	Present
Chihuahua, Mexico	Janos	Janos	Not present
Immediate Potential Sites			
Montana	Custer Creek	Miles City	Unknown
Utah	Cisco Desert	Green River	Present
Wyoming	Thunder Basin National Grassland	Bill	Present

Table 2. Sites at which, pending further evaluation, opportunities for reintroducing black-footed ferrets (*Mustela nigripes*) may exist in 3–10 years (Intermediate Potential Sites; *n* = 70).

State or Province	Site name	Nearest town	Plague status
Arizona	East of Seligman	Seligman	Present
	West of Dilkon, Navajo Indian Reservation	Dilkon	Present
	West of Wupatki National Monument	Flagstaff	Present
Colorado	Pueblo County	Pueblo	Present
	Weld County	Greeley	Present
	Bent County	Lamar	Present
	Baca County	Springfield	Present
	Crowley County	Rocky Ford	Present
	Pueblo Army Depot	Pueblo	Present
	Fort Carson	Colorado Springs	Present
	Comanche National Grassland, Carrizo Unit	Pritchett	Present
	Comanche National Grassland, Timpas Unit, and Pinon Canyon Maneuver Site	La Junta	Present
	Cimarron National Grassland	Springfield	Present
	BLM Twin Lakes Allotment	Alamosa	Present
	Parlin	Gunnison	Present
Kansas	Z-Bar Ranch	Medicine Lodge	Plague free
	Logan County	Colby	Plague free
	Northern Kearny County	Garden City	Plague free
	Greeley County	Horace	Plague free
	Rawlins County	Atwood	Plague free
	Hamilton County	Syracuse	Plague free
	Southern Kearny County	Garden City	Plague free
	Sherman County	Colby	Plague free
Montana	Leachman complex	Billings	Present
	Northern Cheyenne Indian Reservation	Colstrip	Present
	Miles City BLM District	Miles City	Present
	Fort Benton-Roundup-Harlowton area	Roundup	Present
Nebraska	Blue Creek Ranch	Oshkosh	Plague free
	Oglala National Grassland	Chadron	Plague free
New Mexico	Vermejo Park Ranch	Raton	Unknown
	Quay/Curry County interface	Tucumcari	Unknown
	Roosevelt County/Grulla National Wildlife Refuge	Portales	Unknown
	Lea County	Lovington	Unknown
	Union County	Clayton	Unknown
North Dakota	Horse Creek area, Little Missouri National Grassland	Williston	Unknown
	Standing Rock Indian Reservation	North Lemmon	Unknown
	South Unit, Theodore Roosevelt National Park	Dickinson	Plague free
	Little Missouri River	Bowman	Plague free

Table 2. Sites at which, pending further evaluation, opportunities for reintroducing black-footed ferrets (*Mustela nigripes*) may exist in 3–10 years (Intermediate Potential Sites; *n* = 70)—Concluded.

State or province	Site name	Nearest town	Plague status
Oklahoma	Southwest Cimarron County	Boise City	Plague free
	Texas County No. 1	Guymon	Plague free

Saskatchewan, Canada	Grasslands National Park	Swift Current	Unknown

West of Wupatki National Monument

Gunnison's prairie dogs are present at this site north of Flagstaff. A complex of 950 ha was mapped in 2001. Plague has occurred, but the extent has not been quantified (Wagner and Drickamer, 2002; D. Wagner, oral commun., 2003).

Colorado

Black-tailed prairie dogs, white-tailed prairie dogs, and Gunnison's prairie dogs occur in Colorado. Complete location data are not available for Gunnison's prairie dogs since some potential habitat in southwestern Colorado has not been surveyed. White-tailed prairie dogs are also currently being surveyed in northwestern Colorado. Black-tailed prairie dogs occur in all counties in the historical range in the eastern one-third of the State, and recent surveys indicate 255,596 ha of occupied habitat (Colorado Division of Wildlife, 2003). Location data from that survey are not available to the author at this time, however. EDAW, Inc. (2000) identified the 10 counties with the largest amount of active, occupied habitat in the State: Pueblo (8,989 ha), Weld (8,146 ha), Bent (6,914 ha), Baca (5,816 ha), Crowley (5,475 ha), Adams (5,372 ha), Prowers (5,161 ha), Boulder (4,668 ha), Cheyenne (3,717 ha), and Kiowa (3,629 ha). EDAW, Inc. (2000) identified 17 colonies >405 ha and 45 colonies from 203 to 405 ha in the black-tailed prairie dog range in Colorado.

Active Sites

Colorado/Utah

White-tailed prairie dogs occupy the only active black-footed ferret reintroduction site in Colorado. The site is located in northwestern Colorado in Moffat and Rio Blanco Counties and extends into Utah (Uintah County) and Wyoming (Sweetwater County). The Wyoming portion of the site, called Kinney Rim, has virtually no active colonies at the current time. Reintroduction efforts began in 1998. The site is designated a black-footed ferret nonessential, experimental population, and releases of captive black-footed ferrets are ongoing. A small population of black-footed ferrets occurs in the wild there at present. Total occupied prairie dog habitat is approximately 20,250 ha, primarily on U.S. Bureau of Land Management (BLM) land, and plague is present. Potential habitat present in the Colorado portion of this site is estimated at 45,553 ha (M. Lockhart, written commun., 1999–2003).

Intermediate Potential Sites

Pueblo County

Black-tailed prairie dogs occupy this site. The northern half of the county, north of the City of Pueblo, has the largest concentration of colonies and the majority of the 8,989 ha of colonies identified in the county (EDAW, Inc., 2000). This county is primarily private land; therefore, development of black-footed ferret reintroduction sites would require participation by private landowners.

Weld County

Black-tailed prairie dogs occupy this site. The northeastern half of the county, northeast of the City of Greeley, has the largest concentration of colonies and the majority of the 8,146 ha of colonies identified in the county (EDAW, Inc., 2000). This county is primarily private land; therefore, development of black-footed ferret reintroduction sites would require participation by private landowners.

Bent County

Large black-tailed prairie dog colonies occur in the northern and western parts of the county, encompassing the majority of the 6,914 ha identified (EDAW, Inc., 2000). This county is primarily private land; therefore, development of black-footed ferret reintroduction sites would require participation by private landowners.

Baca County

The western one-half of the county, centered on the town of Pritchett, has the largest concentration of black-tailed prairie dog colonies and has the majority of the 5,816 ha identified in the county (EDAW, Inc., 2000). This county is primarily private land; therefore, development of black-footed ferret reintroduction sites would require participation by private landowners.

Crowley County

Large black-tailed prairie dog colonies occur in several places in the county, encompassing 5,475 ha (EDAW, Inc., 2000). This county is primarily private land; therefore, development of black-footed ferret reintroduction sites would require participation by private landowners.

Pueblo Army Depot

Black-tailed prairie dogs occupy this site, which is on a U.S. Army installation. Approximately 1,066 ha of occupied habitat were present before a plague outbreak in 2003. The site is managed by the military and is protected from shooting and poisoning except where black-tailed prairie dogs may constitute a human health hazard (B. Woodson, oral commun., 2003). A large area of occupied habitat also occurs on private lands adjacent to Pueblo Army Depot in El Paso County (EDAW, Inc., 2000).

Fort Carson

Black-tailed prairie dogs occupy this site, which is on a U.S. Army installation. Approximately 1,418 ha of occupied habitat were present before a plague outbreak occurred in 2002 or 2003. The site is managed by the military and is protected from shooting and poisoning except where black-tailed prairie dogs may constitute a human health hazard (B. Woodson, oral commun., 2003). A large area of occupied habitat also occurs on private lands adjacent to Fort Carson, particularly along the southern boundary in Pueblo County (EDAW, Inc., 2000).

Comanche National Grassland, Carrizo Unit

Recent GIS analyses identified 46,395 ha of potential black-tailed prairie dog habitat on this site in Baca County. Potential habitat was defined as land with clay or loamy soil and <5 percent slope. Of this potential habitat, 1,622 ha are currently occupied, with an additional 450 ha occupied outside of potential habitat (primarily on lands mapped as sandy soils, most likely because of inaccurate generalities in the soil map). The Carrizo Unit has extremely fragmented land ownership. Intermingled private lands have even higher densities of colonies (due to higher grazing intensity), but landowners have strongly negative attitudes toward black-tailed prairie dogs. Approximately 2,076 ha of occupied black-tailed prairie dog habitat occurs on National Forest lands, and the amount of occupied habitat on intermingled private lands is unknown (D. Augustine, written commun., 2003).

Comanche National Grassland, Timpas Unit, and Pinon Canyon Maneuver Site

Black-tailed prairie dogs occupy this site, which is on the Timpas Unit and the adjoining U.S. Army Pinon Canyon Maneuver Site. Together these areas provide a large block of land in public ownership with little fragmentation. The Timpas Unit includes a number of private inholdings but is far less fragmented than the Carrizo Unit (above). The amount of occupied habitat in the Timpas Unit is lower than in the past because of plague. A total of 35,917 ha of potential habitat exists, of which 192 ha are currently occupied. An additional 41 ha are outside the area mapped as suitable habitat, for a total of 233 ha on the Timpas Unit. Occupied habitat on the Pinon Canyon Maneuver Site totaled 143 ha when last mapped (D. Augustine, written commun., 2003).

Cimarron National Grassland

Black-tailed prairie dogs occupy this site, which has approximately 16,200 ha of potential habitat, 1,296 ha of which were occupied in 2003. The area is bounded on the north by cropland and on the south by riparian/sand sagebrush (*Artemisia filifolia*) habitat. The Cimarron is separated from the Comanche by sand sagebrush habitat unsuitable for black-tailed prairie dog expansion (D. Augustine, written commun., 2003).

Bureau of Land Management Twin Lakes Allotment

Gunnison's prairie dogs occur at this site on public land in Conejos County, approximately 32 km south of Alamosa. The area supports a large complex of colonies dating back to the 1970s, many of which are old or inactive. Existing occupied habitat is approximately 512 ha (M. Albee, oral commun., 2003).

Parlin

Gunnison's prairie dogs occur at this site, which is on public land 19 km southeast of Gunnison in Gunnison County. The amount of occupied habitat in 1980 was 497 ha (M. Albee, oral commun., 2003).

Kansas

Only black-tailed prairie dogs occur in Kansas. Recent surveys estimate 52,861 ha of occupied habitat in western Kansas (Kansas Black-tailed Prairie Dog Working Group, 2002). The estimate of suitable habitat in Kansas based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 60,181 ha.

Intermediate Sites

Z-Bar Ranch

Black-tailed prairie dogs occupy this site, which is on property owned by Turner Enterprises, Inc., approximately 40 km southwest of Medicine Lodge in Barber County. The site currently supports 101 ha of occupied habitat and is growing steadily. Grassland conservation and black-tailed prairie dog expansion are high priority management objectives (J. Truett, oral commun., 2003).

Logan County

This county contained the largest complex (3,522 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Northern Kearny County

The northern part of this county contained the second largest complex (1,104 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Greeley County

This county contained the third largest complex (826 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Rawlins County

This county contained the fourth largest complex (448 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Hamilton County

This county contained the fifth largest complex (423 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Southern Kearny County

The southern part of this county contained the sixth largest complex (400 ha) of black-tailed prairie dogs in Kansas in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Sherman County

This county had the highest number of colonies and highest occupied area in the 1990–92 survey: 60 colonies and 1,420 ha (Vanderhoof and Robel, 1992, 1994). It also had significant occupied black-tailed prairie dog habitat in 2001 (Kansas Black-tailed Prairie Dog Working Group, 2002).

Montana

Both black-tailed and white-tailed prairie dogs occur in Montana. White-tailed prairie dogs are confined to a very small area near the border with Wyoming and occupy roughly 40 ha of habitat at the present time; therefore, no black-footed ferret reintroduction potential exists for the foreseeable future. Black-tailed prairie dogs occur in the eastern part of the State, and the best estimate of occupied area is 36,450 ha (Montana Prairie Dog Working Group, 2002). The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 97,349 ha.

Active Sites

North-central Phillips County

Black-tailed prairie dogs occupy this site. Black-footed ferret releases have occurred since 1994. Occupied prairie dog habitat was 12,014 ha in the mid-1990s, with 5,457 ha occurring on Fort Belknap Indian Reservation, 4,472 ha on BLM lands, and 2,085 ha on Charles M. Russell National Wildlife Refuge. The area was heavily affected by plague in the late 1990s. The black-footed ferret population is very low at the current time. Land ownership is mixed private, Federal, and tribal (M. Lockhart, written commun., 1999–2003).

Immediate Potential Sites

Custer Creek

Black-tailed prairie dogs occupy this site in Prairie and Custer Counties, which contains >100 colonies and 1,705 ha of occupied habitat on a mixture of State, private, and BLM lands. Plague has not been documented since 1996. Since this site is in an area of checkerboard land status, private interests control the site potential (M. Lockhart, written commun., 1999–2003).

Intermediate Potential Sites

The following locations were identified in the Conservation Plan for Black-tailed and White-tailed Prairie Dogs in Montana (Montana Prairie Dog Working Group, 2002) as 4 of the 10 largest known prairie dog complexes in Montana in 2000.

Leachman Complex

This site is entirely on tribal land in the northwest portion of the Crow Indian Reservation in Yellowstone and Big Horn Counties, and once supported an estimated 4,050–4,860 ha of occupied prairie dog habitat (L. Hanebury, oral commun., 2003). The site included >2,835 ha of occupied prairie dog habitat in recent times but suffered a plague outbreak prior to 2003. Approximately 2,430 ha remained in two colonies in the southwest and central portions of the area in 2003. With translocations, this complex could be viable within a few years (L. Hanebury, oral commun., 2003). Since surveys of suitable habitat on the Crow Indian Reservation have not been completed, sites other than the Leachman site may also exist (L. Hanebury, oral commun., 2003).

Northern Cheyenne Indian Reservation

Suitable habitat exists on the Reservation along the upper Tongue River in Big Horn and Rosebud Counties as well as on adjacent U.S. Forest Service and private lands. Occupied habitat exceeded 5,265 ha prior to a recent plague outbreak. With the help of translocations, this site grew to approximately 2,025 ha in 2003 (L. Hanebury, oral commun., 2003).

Miles City Bureau of Land Management District

Potential habitat exists in Custer and Prairie Counties. This site is mixed private and BLM lands and supported approximately 2,430 ha of prairie dogs in 2000; however, recent plague outbreaks have reduced the size of this complex to approximately 1,337 ha. A change in land ownership resulted in reduced access for mapping, which may have exaggerated the apparent decline in occupied habitat (L. Hanebury, oral commun., 2003).

Fort Benton-Roundup-Harlowton Area

Suitable habitat exists along the upper Musselshell River in Yellowstone, Stillwater, Musselshell, Golden Valley, Wheatland, and Petroleum Counties. The area is mixed private, BLM, and FWS lands and supported >2,430 ha of prairie dogs in 2000 (L. Hanebury, oral commun., 2003).

Nebraska

Only black-tailed prairie dogs occur in Nebraska. Recent surveys estimate 32,400 ha of occupied habitat (M. Fritz, oral commun., 2003) in western Nebraska. The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 55,588 ha.

Intermediate Potential Sites

Blue Creek Ranch

This site, which is owned by Turner Enterprises, Inc., is 16 km northeast of Oshkosh and currently has 8 ha of occupied habitat, which is expanding. Grassland conservation and black-tailed prairie dog expansion are high management priorities (J. Truett, oral commun., 2003).

Oglala National Grassland

This site is located in Sioux and Dawes Counties and currently has 284 ha of occupied black-tailed prairie dog habitat. The Oglala National Grassland will require time to expand existing prairie dog habitat and to consolidate the land base to improve the management potential (S. Larson, written commun., 2003).

New Mexico

Black-tailed and Gunnison's prairie dogs occur in New Mexico. Recent black-tailed prairie dog surveys estimate 24,300 ha of occupied habitat (Johnson and others, 2003) in eastern New Mexico. The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 35,288 ha. Surveys are ongoing for Gunnison's prairie dog, but there is no estimate of current occupied habitat.

Intermediate Potential Sites

Vermejo Park Ranch

This site, which is owned by Turner Enterprises, Inc., is located 40 km southwest of Raton and currently has 689 ha of occupied habitat, which is expanding rapidly. Grassland conservation and black-tailed prairie dog expansion are high priorities (J. Truett, oral commun., 2003).

Quay/Curry County Interface

This site is south of Tucumcari and contains >3,848 ha of occupied habitat, with >2,025 ha contiguous. The mean size of colonies is 19 ha, and the maximum area of a single colony is 152 ha (Johnson and others, 2003).

Roosevelt County/Grulla National Wildlife Refuge

This site is south of Portales and contains >5,265 ha of occupied habitat, with >2,025 ha contiguous. The mean size of colonies is 35 ha, and the maximum size of a single colony is 339 ha (Johnson and others, 2003).

Lea County

This site is northeast of Lovington and contains approximately 9,720 ha of occupied habitat, with >2,025 ha contiguous. The mean size of colonies is 60 ha, and the maximum area of a single colony is 956 ha (Johnson and others, 2003). Plague has recently been active in this area, but impacts have not been quantified (P. Gober, oral commun., 2003).

Union County

This site is southwest of Clayton and contains approximately 3,240 ha of occupied habitat. The mean size of colonies is 41 ha, and the maximum area of a single colony is 292 ha (Johnson and others, 2003).

North Dakota

Only black-tailed prairie dogs occur in North Dakota. Recent surveys estimate 8,303 ha of occupied habitat (Knowles, 2003) in western North Dakota. The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 40,723 ha.

Intermediate Potential Sites

Horse Creek Area, Little Missouri National Grassland

Black-tailed prairie dogs occupy 162 ha at this site in McKenzie County in western North Dakota. The site has strong potential to reach biological readiness for black-footed ferret reintroduction within 10 years, but local support cannot be predicted at this time. The site is included in the most recent land management plans for Little Missouri National Grassland and is plague free (S. Larson, written commun., 2003).

Standing Rock Indian Reservation

Black-tailed prairie dogs occupy 1,215 ha at this site in Sioux County. Colonies are scattered over a large area, and the land base is a checkerboard of private and tribal lands. The area is plague free (S. Larson, written commun., 2003).

South Unit, Theodore Roosevelt National Park

Black-tailed prairie dogs occupy 729 ha at this site in Billings County. In 2002, 61 active colonies were mapped (Knowles, 2003). Knowles (2003) predicted that the site potential on the national park is >2,633 occupied ha based on the amount of suitable habitat present. Additional suitable habitat occurs on adjacent private land, and the area is plague free (Knowles, 2003).

Little Missouri River

Black-tailed prairie dogs occupy this site in Slope County. The site had 345 ha of occupied habitat in 2002. Significant biological potential exists if private land issues can be addressed. The area is plague free (Knowles, 2003).

Oklahoma

Only black-tailed prairie dogs occur in Oklahoma. Recent surveys estimate 26,007 ha of occupied habitat (J. Hoagland, oral commun., 2003) in western Oklahoma. The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 27,806 ha.

Intermediate Potential Sites

Sites in Oklahoma have previously been described as clusters of colonies (M. Lomolino, written commun., 2003).

Cimarron County

This site is in the southwestern corner of the county. Cluster A had 12 colonies totaling 345 ha, and Cluster B had 6 colonies with a total of 652 ha when mapped in 1996–98 (Lomolino and Smith, 2001; M. Lomolino, written commun., 2003).

Texas County No. 1

This site is in the north-central part of the county. Cluster C had 12 colonies with a total of 332 ha when mapped in 1996–98 (Lomolino and Smith, 2001; M. Lomolino, written commun., 2003).

Texas County No. 2

This site is in the east-central part of the county. Cluster D had 18 colonies with a total of 302 ha when mapped in 1996–98 (Lomolino and Smith, 2001; M. Lomolino, written commun., 2003).

Beaver County No. 1

This site is in the east-central part of the county. Cluster E had 10 colonies with a total of 93 ha when mapped in 1996–98 (Lomolino and Smith, 2001; M. Lomolino, written commun., 2003).

Beaver County No. 2

This site is in the south-central part of the county. Cluster F had 34 colonies with a total of 319 ha when mapped in 1996–98 (Lomolino and Smith, 2001; M. Lomolino, written commun., 2003).

South Dakota

Only black-tailed prairie dogs occur in South Dakota. A 2001 survey estimated 64,800 ha of occupied habitat (South Dakota Prairie Dog Work Group, 2001) in western South Dakota. The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 80,786 ha.

Active Sites

Cheyenne River Indian Reservation

Black-tailed prairie dogs occupy this site in Dewey and Ziebach Counties. Total occupied habitat is 17,861 ha in three separate complexes, one of which is 8,424 ha. An operational prairie management program is currently pursuing black-footed ferret reintroduction. There is no history of plague in the area (M. Lockhart, written commun., 1999–2003).

Conata Basin/Badlands National Park

Black-tailed prairie dogs occupy this site in Pennington, Shannon, and Jackson Counties. Total occupied habitat is 6,116 ha, with 4,779 ha on U.S. Forest Service lands and 1,337 ha on National Park Service lands. The estimated potential for the area based on suitable habitat is 7,128 ha. There is no history of plague in the area (M. Lockhart, written commun., 1999–2003).

Rosebud Indian Reservation

Black-tailed prairie dogs occupy 28,350 ha at this site in Todd and Mellette Counties, 18,225 ha of which is on tribal trust lands. There is no history of plague in the area (M. Lockhart, written commun., 1999–2003).

Intermediate Potential Sites

Pine Ridge Indian Reservation

Black-tailed prairie dogs occupy 20,250–40,500 ha on tribal lands at this site in Shannon County. The site has the biological capacity to support a large black-footed ferret population but may be constrained by social, cultural, and political factors (S. Larson, written commun., 2003).

Standing Rock Indian Reservation

Black-tailed prairie dogs occupy 2,835 ha at this site in Corson County. Black-tailed prairie dogs are scattered over a large area, and the land base is a mixture of private and tribal. There is no history of plague in the area (S. Larson, written commun., 2003).

Lower Brule Indian Reservation

Black-tailed prairie dogs occupy 11,745 ha at this site in Stanley and Lyman Counties. There is no history of plague in the area (S. Larson, written commun., 2003).

Wind Cave National Park

Black-tailed prairie dogs occupy 689 ha at this site in Custer County. Biologically, this site could be ready for black-footed ferret reintroduction within a few years, and the National Park Service is supportive. There is no history of plague in the area (S. Larson, written commun., 2003).

Grand River National Grassland

Black-tailed prairie dogs occupy 648 ha at this site in Perkins and Corson Counties. Biologically, this site is not ready for black-footed ferret reintroduction, as it needs time for black-tailed prairie dogs to expand occupied habitat. The U.S. Forest Service needs to consolidate its land base; however, it has identified the site for prairie dog expansion in the most recent land management plan. There is no history of plague in the area (S. Larson, written commun., 2003).

Bad River Ranches

Black-tailed prairie dogs occupy this site on lands owned by Turner Enterprises, Inc., in Stanley and Jones Counties, 16 km southwest of Pierre. The site currently has 506 ha of occupied habitat and is growing steadily. Grassland conservation and black-tailed prairie dog expansion are high priorities. There is no history of plague in the area (J. Truett, oral commun., 2003).

Smithwick Area, Buffalo Gap National Grassland, Fall River Ranger District

Black-tailed prairie dogs occupy 405 ha at this site in Custer County. From a biological standpoint, the site could be ready for black-footed ferret reintroduction within 5 years. The site was included in the most recent land management plan for Buffalo Gap National Grassland. There is no history of plague in the area (S. Larson, written commun., 2003).

Texas

Only black-tailed prairie dogs occur in Texas. Ongoing surveys currently estimate 79,785 ha of occupied habitat in western Texas (D. Holdstock, oral commun., 2003). The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 118,717 ha.

Intermediate Potential Sites

Rita Blanca National Grassland

Black-tailed prairie dogs occupy this site north of Dalhart in Dallam County. The site was identified by Lair and Mecham (1991) as having >4,050 ha of occupied habitat, with 49 colonies >41 ha in size and >1.0 percent of the land area in prairie dog colonies (Lair and Mecham, 1991; Ernst, 2001).

Muleshoe National Wildlife Refuge

Black-tailed prairie dogs occupy this site northwest of Lubbock in Bailey County. It was identified by Lair and Mecham (1991) as having >2,835 ha of occupied habitat, with 25 colonies >41 ha in size and >1.0 percent of the land area in prairie dog colonies (Lair and Mecham, 1991; Ernst, 2001).

Sherman County

Black-tailed prairie dogs occupy this site north of Dumas. It was identified by Lair and Mecham (1991) as having >3,240 ha of occupied habitat, with 32 colonies >41 ha in size and 1.5 percent of the land area in prairie dog colonies (Lair and Mecham, 1991; Ernst, 2001).

Deaf Smith County

Black-tailed prairie dogs occupy this site southwest of Amarillo. It was identified in Lair and Mecham (1991) as having >5,670 ha of occupied habitat, with 55 colonies >41 ha in size and 1.5 percent of the land area in prairie dog colonies (Lair and Mecham, 1991; Ernst, 2001).

Utah

Gunnison's prairie dogs and white-tailed prairie dogs occur in Utah. Data on locations and occupied area are still being developed for both species.

Active Sites

There is one active black-footed ferret reintroduction site in Utah (see discussion under Colorado).

Immediate Potential Sites

Cisco Desert

White-tailed prairie dogs occur at this potential site identified by the Black-footed Ferret Recovery Program. The site was mapped in 1986 (Boschen, 1986) and again in 2002 (Seglund and others, 2005a). The site is on public land in Grand County in east-central Utah along I-70 from east of Green River to the Colorado border. Land ownership is mixed private, State, and Federal (M. Lockhart, written commun., 1999–2003).

Intermediate Potential Sites

Buckhorn and Crescent Junction

White-tailed prairie dogs occupy this site in Emery and Grand Counties in south-central Utah. According to C. McLaughlin (oral commun., 2003), Cedar Creek Associates mapped 7,644 ha, including both active and inactive colonies, in this complex on public lands in 1985. The area mapped extended south of Huntington to I-70 along State Highway 10, east to State Highway 6, and along I-70 to Thompson Springs. In 2002, mapping within the same area recorded 7,881 ha, including active and inactive colonies, approximately a 3 percent increase from 1985 (C. McLaughlin, written commun., 2003).

Twelvemile Flat

White-tailed prairie dogs occur at this site on public lands in the BLM Diamond Mountain Resource Area west and north of Green River in northeastern Utah. Twelvemile Flat contained 363 ha of occupied habitat in 1985. The site was resurveyed in 1992–93 (Cranney and Day, 1994) and found to have 771 ha of occupied habitat, slightly over double the amount present in 1985. In 2002, mapping located 365 ha of occupied habitat (C. McLaughlin, written commun., 2003).

Eightmile Flat (Myton Bench)

White-tailed prairie dogs occur at this site on public lands in the BLM Diamond Mountain Resource Area west and north of Green River in northeastern Utah. Eightmile Flat contained 2,673 ha of occupied habitat in 1985. The site was resurveyed in 1999 and found to have increased by 9 percent, to 2,936 ha of occupied habitat (C. McLaughlin, written commun., 2003).

Sunshine Bench/Brush Creek

White-tailed prairie dogs occur at these sites on public lands in the BLM Diamond Mountain Resource Area west and north of Green River in northeastern Utah. The sites were mapped to evaluate their suitability for black-footed ferret reintroduction in 1992–93 (Cranney and Day, 1994). The Sunshine Bench complex contained 2,085 ha of occupied habitat in 1992–93, while the adjacent Brush Creek area contained 145 ha of occupied habitat. The combined occupied area of Sunshine Bench and Brush Creek was 7,837 ha in 2002 (C. McLaughlin, written commun., 2003).

Buckhorn Flat

White-tailed prairie dogs occur at this site on public lands 56 km south of Price. The estimated occupied habitat at the site is 2,412 ha (A. Seglund, written commun., 2003).

Wyoming

Black-tailed and white-tailed prairie dogs occur in Wyoming. Black-tailed prairie dogs occur in the eastern one-third of the State. Recent occupied habitat estimates range widely, but the current estimate is 50,625 ha (M. Grenier, written commun., 2003). The estimate of suitable habitat based on the Bailey Ecoregion habitat model (Luce, 2003) is a minimum of 64,059 ha. White-tailed prairie dogs occur in the west-central part of the State, and surveys are underway to estimate occupied habitat.

Active Sites

Shirley Basin

Shirley Basin/Medicine Bow is the only active black-footed ferret reintroduction site in Wyoming and occurs in the white-tailed prairie dog range. The site was fully mapped in 1989 (Conway, 1989) and again in 1990 by using a combination of aerial transects and ground verification (Hnilicka and Luce, 1992). In 1990, intensive mapping showed the complex to contain 59,726 ha (Parrish and Luce, 1990). Captive-bred black-footed ferrets were released from 1991 to 1994, and the highest number of black-footed ferrets found on subsequent surveys was in 2004, when 85 individuals were located during spotlight surveys (Grenier and others, 2004) of less than 20 percent of the occupied habitat (based on 1990 mapping data). Therefore, considerable potential exists for a large, contiguous population of black-footed ferrets or several subpopulations. It is important to note that both prairie dogs and black-footed ferrets have persisted with plague present since at least 1987 (Orabona-Cerovski, 1991).

Immediate Potential Sites

Thunder Basin National Grassland

Black-tailed prairie dogs occur at this site in Campbell, Converse, and Weston Counties. The site is identified as a black-footed ferret reintroduction site in the current Forest Plan for the Medicine Bow National Forest/Thunder Basin National Grassland. There was no history of plague before 2001 when an extensive die-off occurred, reducing occupied habitat by over 4,050 ha. Recovery is occurring. Prior to the plague outbreak, occupied black-tailed prairie dog habitat was 8,079 ha, including 7,290 ha on U.S. Forest Service land and 789 ha on State land. The U.S. Forest Service estimates that there are 193,590 ha of potential habitat on its lands in this area of Wyoming (T. Byer, written commun., 2003).

Intermediate Potential Sites

Meeteetse

White-tailed prairie dogs occupy this site west of Meeteetse in Park County. This site, from which all of the black-footed ferret captive breeding stock was taken, had 4,930 ha of occupied habitat in 1982, just after black-footed ferrets were first discovered, and a high population of 129 black-footed ferrets (43 adults, 25 litters) in 1984. Because of plague in white-tailed prairie dogs, occupied habitat was reduced to roughly 2,029 ha by 1989, 2 years after all extant black-footed ferrets were captured for captive breeding (Black-footed Ferret Advisory Team, 1990). The site has not shown significant recovery of prairie dogs since 1989 (Biggins, 2003). The habitat capability of the site remains, including old burrow systems, so the potential exists for recovery to sufficient occupied habitat for black-footed ferret reintroduction within 10 years.

Bolton Ranch

White-tailed prairie dogs occupy this site west of Saratoga in Carbon County. Land ownership is a checkerboard of public and private lands. The site had 4,500 ha of occupied habitat in 1989 when it was first surveyed (Conway, 1989). No surveys have been conducted since then (Grenier and others, 2003; R. Luce, written commun., 1995).

Carter

White-tailed prairie dogs occupy this site 32 km southeast of Kemmerer, on BLM lands in Lincoln County. The site has not been fully mapped or surveyed to determine prairie dog density. It contained more than 4,050 ha of occupied habitat when partially mapped in the 1980s (Grenier and others, 2003; R. Luce, written commun., 1995). The Carter site is potentially connected to another site (Moxa) which is 32 km north of Kemmerer, indicating that an extremely large complex may exist in this area. Moxa was identified in the mid-1990s when 17,415 ha of occupied habitat were mapped, and the site has not been resurveyed (Grenier and others, 2003; B. Luce, unpub. data, 1995).

Cumberland

White-tailed prairie dogs occupy this site southwest of Kemmerer in Lincoln County. Land ownership is a checkerboard of public and private lands. The site was fully mapped and preliminary density data were collected in the 1980s (Clark and Campbell, 1981). Occupied habitat was 4,293 ha. The site has not been remapped.

Fifteenmile

White-tailed prairie dogs occupy this site on BLM land 40 km west of Worland in Hot Springs County. The site contained 3,078 ha of occupied habitat when mapped in the 1980s and has not been remapped (Grenier and others, 2003; R. Luce, written commun., 1995).

Flaming Gorge

White-tailed prairie dogs occupy this site on BLM land 64 km south of Green River in Sweetwater County. The site was intensively mapped in 1989 and contained 3,049 ha of occupied habitat (Martin and Luce, 1990). It has not been remapped.

Shamrock Hills

White-tailed prairie dogs occupy this site on BLM land 16 km north of Rawlins in Carbon County. The site was mapped in the 1980s and had >4,050 ha of occupied habitat. The site has not been remapped (Grenier and others, 2003; R. Luce, written commun., 1995).

Kaycee

Black-tailed prairie dogs occupy this site west of the town of Kaycee in Johnson County, primarily on private land. This site was discovered recently and has not been mapped, but it is estimated that >1,215 ha of occupied habitat are present (R. Luce, unpub. data, 2003).

Sheridan Local Training Center

Black-tailed prairie dogs occupy this site on a U.S. Army installation adjacent to Sheridan in Sheridan County. The site contained 284 ha of occupied habitat in 2001, and adjacent private and State lands had a substantial amount of additional occupied habitat (R. Luce, unpub. data, 2003).

Canada

Only black-tailed prairie dogs occur in Canada, which is the northern extent of the range of the species.

Intermediate Potential Sites

Grasslands National Park and Vicinity

Black-tailed prairie dogs occur at this site in Saskatchewan, 160 km south of Swift Current. The site has 25 colonies containing a minimum of 1,044 ha. It has been partially mapped since 1993 but was fully mapped for comparative purposes from 1998 to 2002 and had a stable occupied area for that time period (P. Fargey, written commun., 2003).

Mexico

Black-tailed prairie dogs occur in northern Mexico, the southern extent of the range, and are the only species of prairie dog in Mexico in the historical range of the black-footed ferret.

Active Sites

Janos

Black-tailed prairie dogs occur at this site north of Nuevo Casas Grandes in Chihuahua. Estimated occupied prairie dog habitat is 19,845 ha, and the potential suitable habitat is 55,080 ha. Land ownership is divided between Federal Ejidos and private ownership. This is a large prairie dog complex and may have the potential for one contiguous black-footed ferret population or several subpopulations. No management plan exists for the area (R. List, oral commun., 2003).

Intermediate Potential Sites

There are no Intermediate Potential Sites in Mexico.

Discussion

It is clear from past efforts that a “best and only” methodology for successful black-footed ferret reintroduction has not been unequivocally established. The 1988 recovery plan (U.S. Fish and Wildlife Service, 1988) encourages experimentation. It also emphasizes a management philosophy important for both establishing and maintaining reintroduced populations whereby the broadest possible distribution of black-footed ferrets might be achieved. This risk management approach is important to protect the species overall from adverse impacts that may occur locally, especially disease.

Preparation of this paper does not constitute a proposed State or Federal action at any of the proposed sites; it is merely a conceptual approach to aid in black-footed ferret recovery. Many steps will be required before any site can eventually receive ferrets; however, I do not believe that it is necessary or appropriate to wait for final biological, social, and political issues to be addressed at a given site in order for it to be considered for the list of potential reintroduction sites. This conceptual exercise identifies sites based entirely on either a minimum area of occupied prairie dog habitat or a small but increasing prairie dog population at a site that has the habitat characteristics necessary to support black-footed ferrets. I recognize that myriad actions would be necessary before black-footed ferrets could actually be released at a given site, especially where private lands are involved.

The general limitation of lack of habitat or habitat availability is shared with many other species. But in the case of the black-footed ferret, which is a highly specialized prey/habitat obligate of prairie dogs, dependence has proven to be especially catastrophic because of the dramatic reduction of its prey over the past century by adverse land-use practices such as prairie conversion to cropland, poisoning to reduce forage competition with domestic livestock, and sylvatic plague, an exotic disease catastrophic to prairie dogs (Cain and others, 1972; Hansen, 1988; Cully, 1993; Van Pelt, 1999; U.S. Fish and Wildlife Service, 2000; Cully and Williams, 2001; Antolin and others, 2002; Luce, 2003). Despite these potential conflicts and future challenges, identification of appropriate sites for black-footed ferret reintroduction has been ongoing for over two decades.

Although occupied prairie dog habitat has been significantly reduced since western settlement (Hoogland, 1995; Miller and Cully, 2001), it has been only in the last decade that the degree of both the quantity and quality of this loss relative to potential black-footed ferret recovery has been recognized. At present there may not be sufficient occupied prairie dog habitat in total in the historical ranges of the black-tailed prairie dog, white-tailed prairie dog, and Gunnison’s prairie dog, either in quantity or quality, for the black-footed ferret to be fully recovered, especially if black-footed ferret populations are to be broadly represented geographically as a precaution against depressant stochastic influences (M. Lockhart, written commun., 1999–2003).

The 1988 Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988) set a downlisting goal for the species at 1,500 adults in 10 or more populations dispersed across its historical range, with no single population being less than 30 adults. Downlisting the species would move it from endangered to threatened status but would not represent complete recovery. Delisting the black-footed ferret through recovery sufficient to obviate its endangered status and permit its removal from the endangered species list (pursuant to the Endangered Species Act of 1973, as amended) would require even more recovery sites.

I suggest that it may be necessary to evaluate an order of magnitude more sites to achieve complete recovery and delisting, or 100 sites across the historical range of the species. These sites should be widely dispersed and represent the variety of habitats available, including different prairie dog species, ecological circumstances, disease prevalence, and the like. Since some sites may prove not to be usable for biological, social, or other reasons, or may not be successful, it will be necessary to consider many.

Plague is a confounding factor. Annual monitoring to document plague activity and the amount of habitat affected would assist prairie dog and black-footed ferret management. Continuing research on the mechanisms by which plague is spread, pretreatment of prairie dogs, and posttreatment of burrows to kill fleas and thus reduce the magnitude of an epizootic may allow practical management of the disease in the next 10 years. Meanwhile, maintaining spatial distribution of prairie dog complexes and isolated colonies over the entire range to act as reservoirs to replace prairie dogs lost to plague, as well as development of black-footed ferret reintroduction sites east of the plague line (in the plague-free area), will greatly assist in managing the impacts of the disease on prairie dogs.

In my opinion, data presented by Cully and Williams (2001) suggest that a fundamental change may be occurring in prairie dog ecology whereby some large colonies, especially those of black-tailed prairie dogs, may not persist when repeatedly challenged by plague. Persistence of only small colonies or complexes may have serious implications for black-footed ferret recovery. Extensive habitat will be necessary for reintroduction success, especially in the absence of management, and few large sites may persist at their full habitat capability in the face of repeated plague epizootics. On the other hand, recent surveys of white-tailed prairie dogs and black-footed ferrets in Shirley Basin, Wyo., indicate that these areas may have proportionately higher value than previously thought because both prairie dogs and black-footed ferrets have maintained significant populations in the presence of plague since monitoring was begun in 1991 (Luce, 2002; Grenier and others, 2004). In fact, both white-tailed prairie dog and black-footed ferret numbers increased despite more than 10 years of active plague (Grenier and others, 2004).

Status of Prairie Dog Conservation

Since black-footed ferret recovery and prairie dog management issues are closely tied, the future of the black-footed ferret essentially depends on developing effective management of black-tailed, white-tailed, and Gunnison’s prairie dogs. The Black-tailed Prairie Dog Conservation Team (later just the Prairie Dog Conservation Team), which includes representatives from 12 State wildlife agencies, has been working since 1998 to develop effective conservation for prairie dogs. The team first developed the Black-tailed Prairie Dog Conservation Assessment and Strategy (Van Pelt, 1999), which was followed by an addendum called the Black-tailed Prairie Dog Multi-State Conservation Plan (Luce, 2003), a guideline for development of State black-tailed prairie dog management plans. Black-tailed prairie dog management plans have been completed in Colorado, Kansas, Montana, New Mexico, North Dakota, Oklahoma, and Texas. Draft management plans are moving toward finalization in South Dakota and Wyoming. Arizona has a draft management plan and is currently evaluating black-tailed prairie dog reintroduction, while Nebraska does not expect to continue development of a management plan.

The Black-tailed Prairie Dog Multi-State Conservation Plan includes several provisions that are important to black-footed ferret recovery, two areas of which are of the greatest significance. First, the objectives for occupied area, shown in table 3, indicate a commitment on the part of a majority of the States with black-tailed prairie dogs to increase the occupied area from 631,127 ha to 685,946 ha by 2011 (Luce, 2003). Second, the Multi-State Conservation Plan sets other target objectives for the United States as follows:

1. Maintain at least the current occupied area of black-tailed prairie dog habitat in the two complexes greater than 2,025 ha that now occur on and adjacent to Conata Basin-Buffalo Gap National Grassland, S. Dak., and Thunder Basin National Grassland, Wyo.
2. Develop and maintain a minimum of nine additional complexes greater than 2,025 ha (with each State managing or contributing to at least one complex) by 2011. A State could contribute to a 2,025 ha complex along a State boundary by cooperating with the adjacent State to manage part of the complex. A similar agreement could be developed between a State and a Native American tribe.
3. Achieve and maintain at least 10 percent of total occupied habitat in colonies or complexes greater than 405 ha by 2011.

Table 3. Estimates of historical, current, gross, and suitable black-tailed prairie dog (*Cynomys ludovicianus*) habitat, and the 10-year minimum habitat objective (Luce, 2003). Native American tribes in Montana, South Dakota, and North Dakota will set an occupied-area objective independent of the States.

State	Historical potential habitat[1] (ha)	Current occupied habitat[2] (ha)	Gross habitat[3] (ha)	Suitable habitat[4] and minimum 10-year objective[5] (ha)
Arizona	2,854,090	0	2,854	1,861
Colorado	11,077,916	255,596	110,779	103,588
Kansas	14,513,206	52,861	61,039	60,181
Montana	24,479,316	36,450	120,401	97,349
Nebraska	14,594,350	32,400	59,430	55,588
New Mexico	15,803,686	24,300	39,148	35,288
North Dakota	4,473,334	8,303	44,733	40,723
Oklahoma	8,750,479	26,007	28,702	27,806
South Dakota	11,851,333	64,800	88,339	80,786
Texas	31,829,943	79,785	125,933	118,717
Wyoming	8,937,378	50,625	75,524	64,059
Total	149,165,031	631,127	756,882	685,946

[1] Historical potential habitat = total potential habitat (not occupied habitat) encompassed within the range of the black-tailed prairie dog (as mapped by Hall, 1981). See Luce (2003) for further explanation.

[2] Current occupied habitat = estimates provided by the individual States.

[3] Gross habitat = total area of core range × 0.01 + area of secondary range × 0.001. Core range was defined as Bailey Ecosections dominated by shortgrass prairie plants and having black-tailed prairie dogs on the list of native fauna. Secondary range was defined as Bailey Ecosections dominated by plants not associated with shortgrass prairie, or having historically suitable habitat but a current sociopolitical climate unfavorable for prairie dog management. See Luce (2003) for additional details.

[4] Suitable habitat = gross habitat minus habitat with >10% slope and habitats such as large bodies of water, badlands, wetlands, forests, or other features not used by prairie dogs. Agricultural lands were included if they met the slope criterion.

[5] Minimum 10-year objective = objective for minimum area of occupied prairie dog habitat in each State, and total for the 11 States, by 2011.

4. Maintain distribution across at least 75 percent of the counties in the historical range or at least 75 percent of the historical geographic distribution. Ten States currently meet this objective (Arizona does not since the black-tailed prairie dog was extirpated), and all but Nebraska and Arizona have black-tailed prairie dogs in 100 percent of the counties in the historical range. This objective addresses the need to maintain all prairie dog colonies, whatever the size or location, throughout the range. State management plans will deal directly with management of complexes and individual, isolated colonies.

Management strategies for black-tailed prairie dogs on tribal lands were prepared for the Intertribal Prairie Ecosystem Restoration Consortium in January 2002 (T. Vosburgh, oral commun., 2003). The goal is to develop and implement management programs for the conservation of prairie dog habitat. These management strategies were revised on February 4, 2002, following review and comment from participating tribes, the U.S. Fish and Wildlife Service, and the Interstate Coordinator for the 12-State Prairie Dog Conservation Team. The consortium convened twice in 2002 and is working with other groups and agencies to move prairie dog management and conservation forward. The tribes have drafted plans to ensure that prairie dog populations and habitat are maintained. The Lower Brule and Fort Belknap Indian Reservations have final prairie dog management plans in place, and draft plans have been prepared for the Fort Berthold, Northern Cheyenne, Crow Creek, and Rosebud Indian Reservations.

The States of Wyoming, Colorado, Utah, and Montana developed a conservation assessment for the white-tailed prairie dog in 2005 (Seglund and others, 2005a), as did the States of Arizona, New Mexico, Colorado, and Utah for the Gunnison's prairie dog (Seglund and others, 2005b). When a conservation strategy is developed for the Gunnison's prairie dog, complexes of colonies will be identified, and other sites with black-footed ferret reintroduction potential may thus become apparent.

Summary and Recommendations

The black-footed ferret recovery program has faced and overcome several obstacles to reach the point where it is today. Foremost were capture of the wild population at Meeteetse, Wyo., captive breeding, development of release strategies, and release site identification based on habitat suitability and other factors. Given that those obstacles to success were overcome, I believe that, at the present time, continued progress on black-footed ferret recovery depends upon identification and active management of additional reintroduction sites. To that end, I identify 70 sites in the historical range of the black-footed ferret that might meet the biological and habitat suitability requirements for reintroduction of black-footed ferrets within 3–10 years, contingent upon directed management emphasis, State and Federal agency management priorities, and, if on private land, landowner concurrence based on agreements or incentives.

The Black-footed Ferret Recovery Implementation Team and Prairie Dog Conservation Team are encouraged to:

- Cooperate closely with State and Federal agencies and eight tribal governments to move toward the targets set in the Black-tailed Prairie Dog Multi-State Conservation Plan and State and tribal management plans.
- Assist the White-tailed and Gunnison’s Prairie Dog Working Groups to develop management plans for both species.
- Cooperate to evaluate the sites presented in this paper and develop strategies to begin management of as many sites as possible for black-footed ferret reintroduction within 10 years.
- Support and advance the High Plains Partnership landowner incentive program and/or other programs designed to bring about landowner participation in grassland species management.

Acknowledgments

Pete Gober provided insight for, and extensive assistance with, preparation of this paper. Brian Miller, Sterling Miller, Larry Nelson, Bob Oakleaf, and Bill Van Pelt provided comments and suggestions. Charlene Beskin produced figure 1.

A Habitat-based Technique To Allocate Black-footed Ferret Recovery Among Jurisdictional Entities

By Andrea E. Ernst,[1] Aaron L. Clark,[2] and Donald R. (Pete) Gober[3]

Abstract

We offer a technique to allocate a hypothetical black-footed ferret (*Mustela nigripes*) recovery goal in an equitable fashion across the historical range of ferrets. A geographic information system (GIS) was used to predict the distribution of prairie dog (*Cynomys* spp.) habitat where the black-footed ferret historically occurred. Proportions of predicted habitat by jurisdictional entity provided a foundation to allocate a hypothetical delisting of the black-footed ferret. Subject to modification, this technique is presented as an example to bring long-term ferret recovery into finer focus at a national scale. In addition, we offer this technique to encourage a broader assessment of future reintroduction sites, to inspire creative thinking on how recovery goals could be allocated across the historical range, and to motivate collaborative efforts among Federal and State agencies, conservation groups, and private landowners to increase the likelihood of successful recovery of the black-footed ferret.

Keywords: black-footed ferret, *Cynomys*, geographic information system, GIS, *Mustela nigripes*, prairie dog, predicted habitat model, recovery

Introduction

The ultimate goal of the Endangered Species Act is recovery and subsequent preservation of threatened or endangered species (U.S. Fish and Wildlife Service, 2002a). Achievement of this goal can be defined in terms of downlisting, which is the reclassification of a species from endangered to threatened status, or delisting, which is the removal of a species from the Federal List of Endangered and Threatened Wildlife and Plants (Cole, 1989; U.S. Fish and Wildlife Service, 2002a). Downlisting and delisting result from successful recovery efforts; delisting occurs when protection of a species is no longer deemed necessary. To coordinate recovery efforts among Federal, State, and local agencies, the U.S. Fish and Wildlife Service prepares recovery plans that outline necessary procedures to achieve downlisting and delisting. Recovery plans identify specific tasks aimed at making a species a viable, self-sustaining component of its ecosystem (Cole, 1989; U.S. Fish and Wildlife Service, 2002b).

The first recovery plan for the critically endangered black-footed ferret (*Mustela nigripes*) was approved in 1978. At that time, no ferrets were known to exist in the wild (U.S. Fish and Wildlife Service, 1988; Cole, 1989). The subsequent discovery of a wild population of ferrets in Wyoming necessitated revision of the recovery plan. The main revision was a shift in management emphasis from free-ranging ferret populations to captive breeding and reintroduction (Biggins and Thorne, 1994). The revised recovery plan (U.S. Fish and Wildlife Service, 1988) placed the ferret program in a national scope and outlined steps “to ensure immediate survival of the black-footed ferret by: (1) increasing the captive population of black-footed ferrets to a census size of 200 breeding adults by 1991; (2) establishing a pre-breeding census population of 1,500 free-ranging black-footed ferret breeding adults in 10 or more populations with no fewer than 30 breeding adults in any population by the year 2010; and (3) encourage the widest possible distribution of reintroduced black-footed ferret populations” (U.S. Fish and Wildlife Service, 1988, p. 19).

As stated in the third step in the recovery plan, reintroduction of ferrets should be considered in the context of their historical geographic range. Selection of reintroduction sites should be based on several biological considerations, including the vulnerability of ferrets to demographic stochasticity (survival of population subgroups); environmental stochasticity (diseases, changes in predator densities); and genetic stochasticity (effects of inbreeding and loss of genetic variation through drift) (Shaffer, 1981; Groves and Clark, 1986; Clark, 1994). To be successful, however, black-footed ferret recovery must also involve more than biological considerations (Kleiman and others, 2000), and a variety of issues, including availability and ownership of potential habitat, should be considered when selecting reintroduction sites.

To date, selection of reintroduction sites has focused on identifying, protecting, and developing the most promising and

largest reintroduction locations; however, large reintroduction sites may not be developed as rapidly as needed, and availability of these sites should not limit overall ferret recovery (Clark, 1994). New sites need to be identified, and maintenance of a few large sites should not necessarily preclude other, smaller recovery areas. To contribute to the overall recovery effort and to fulfill State recovery objectives, a strategy that incorporates recovery areas of various sizes would maximize the potential to secure ferret populations in the wild (U.S. Fish and Wildlife Service, 1988).

Additional challenges in ferret recovery include successful ferret reintroduction and effective long-term management of the sites (Reading and Miller, 1994). Selection of potential reintroduction sites is problematic and controversial and has suffered from disagreements among multiple interest groups, conflicting objectives, biological uncertainty, sociopolitical constraints, and intense public scrutiny (Maguire and others, 1988). Given these challenges, field biologists, veterinarians, and administrators representing Federal, State, and private agencies must provide a means by which to allocate ferret recovery in an equitable fashion. Equitable allocation will encourage participation by all entities and help place long-term ferret recovery in a national scope. To assist in meeting these challenges, we offer a habitat-based technique to allocate reintroduction efforts among jurisdictional entities. This technique is based on quantifying the relative amount of potential habitat across the geographic range. We offer this technique only as a test case to help bring long-term ferret recovery into finer focus at the national scale. Further, our technique will potentially broaden current assessments of future reintroduction sites and encourage cooperation across the extended network of people involved in the survival of the black-footed ferret.

Methods

Digital Data Layers

Recent advances in computer-aided mapping, combined with accessibility of geographic information system (GIS) data sets, enable production of digital maps depicting distributions of predicted habitat at a spatially detailed, landscape scale. Historical black-footed ferret specimens were recorded in association with three species of prairie dogs (*Cynomys* spp.), including the black-tailed prairie dog (*C. ludovicianus*), white-tailed prairie dog (*C. leucurus*), and Gunnison's prairie dog (*C. gunnisoni*) (Anderson and others, 1986). Further, black-footed ferret habitat is often defined in terms of prairie dog colonies. Thus, we created predictive habitat distribution models for the three species of prairie dogs. We defined and restricted the geographic area used in the predictive models by using the comprehensive prairie dog range maps as described by Hall (1981). These maps characterize the extremes of the area where prairie dog species were found historically and incorporate all known specimen records, including marginal habitats and disjunct populations. The range distribution maps provided by Hall (1981) were scanned with a desktop scanning device at 800 dots per inch. The digital images were saved in a tagged image file format to provide baseline GIS coverages. These images were registered to geographic coordinates, and distribution boundaries were digitized for each prairie dog species. We did not include the Utah prairie dog (*C. parvidens*) because evidence suggests that black-footed ferrets were not associated with this species (Anderson and others, 1986).

Collection records demonstrate that ferrets, until the first decades of the 20th century, were distributed over 40 million ha in 12 States and 2 Canadian Provinces (Anderson and others, 1986; Clark, 1986, 1987). County jurisdictional boundaries were acquired from the National Atlas of the United States® (http://www.nationalatlas.gov), imported into ArcGIS® 8.3 software (Environmental Systems Research Institute, Inc., Redlands, Calif.), and dissolved by State attributes, producing boundaries at a scale of 1:100,000 for the 12 States in which the black-footed ferret historically occurred.

Digital data sets depicting landscape attributes were chosen based on the availability and uniformity of data across the geographic range. We used the U.S. Geological Survey (USGS) National Land Cover Dataset (NLCD; http://landcover.usgs.gov/natllandcover.asp) to provide an estimate of current land cover. This data set depicts generalized land cover categories labeled agriculture, urban areas, forests, wetlands, grasslands, and shrublands with a 30-m spatial resolution. The NLCD was created from Landsat 5 Thematic Mapper satellite imagery digitally captured in 1992, produced by the Earth Resources Observation System Data Center. The NLCD was downloaded in complete State sections, which included a 300-m (10-pixel) buffer added to each outer State boundary. The data were then imported into ERDAS IMAGINE® 8.6 (Leica Geosystems Geospatial Imaging, LLC, Norcross, Ga.) and projected into a common coordinate system. Each State was clipped to the individual jurisdictional boundaries.

We used the USGS National Elevation Dataset (NED) to provide continuous, seamless elevation information at a 30-m spatial resolution. We downloaded the NED (http://ned.usgs.gov) in individual 1:250,000 quadrangles. The individual quadrangles were then map-joined to create one complete data layer for each State. Each data layer, as with all GIS data used in the model, was projected to a common coordinate system (Albers Equal Area projection). This projection is used in the United States and other countries that have a larger east-west than north-south extent because it preserves the area of the displayed features over the entire map with the same proportional relationship as the actual geographic areas they represent (Kennedy and Kopp, 2000). The individual data sets were then clipped to the State jurisdictional boundaries.

Predicted Habitat Models

We created digital models of predicted prairie dog habitat based on a set of landscape attributes and wildlife-habitat relationships. The wildlife-habitat relationships were based on attributes important in defining prairie dog habitat, such as land cover and topographic gradient (Koford, 1958; Clippinger, 1989). Generalized land cover categories considered suitable prairie dog habitat were grassland, shrubland, small grains, row crops, and pastures. Land cover types considered unsuitable were forests, water, and snow. Residential, wetland, and fallow land cover types may provide some prairie dog habitat; however, we considered these contributions minimal and placed these land cover types in the unsuitable category.

Topographic gradient was an additional landscape attribute used to predict prairie dog habitat. We used an algorithm in ERDAS IMAGINE 8.6 to derive percent slope from the NED. Slopes of 0–10 percent were considered suitable habitat. Although prairie dogs may occur on slopes greater than 10 percent, black-tailed prairie dogs usually build on slopes of less than 10 percent (Koford, 1958; Dalstead and others, 1981; Clippinger, 1989). Therefore, the remaining slope categories (11 percent and greater) were considered unsuitable habitat for all prairie dog species.

The Spatial Modeler module of ERDAS IMAGINE 8.6 was used to produce the individual predicted habitat models for each State. We used the additive overlay technique, which combined each individual data layer as an equally weighted component in the model. Although this process is referred to as additive, the file produced depicts the specific combination of the appropriate land cover and slope attributes selected as suitable prairie dog habitat. The predicted models for each State were then clipped to the individual range boundaries and merged into one complete data set. The result was a predicted habitat model for each prairie dog species.

The final step in modeling predicted habitat was removal of small, isolated tracts. Our models were produced at a 30-m spatial resolution, which we considered to be below the minimum habitat area required for black-footed ferrets. Minimum habitat area can be defined as the minimum amount of contiguous habitat that is required before an area will be occupied by a species (Clippinger, 1989). Because the different prairie dogs species afford different ferret carrying capacities, the size of suitable reintroduction areas ultimately depends on densities of prey. For example, ferrets have been shown to occur at densities of one adult black-footed ferret per 40–60 ha in white-tailed prairie dog colonies (Forrest and others, 1985; Richardson and others, 1986; U.S. Fish and Wildlife Service, 1988). Hillman and others (1979) found that 6 of 11 observed ferret litters occupied black-tailed prairie dog colonies greater than 40 ha. Further, black-tailed prairie dogs tend to be more gregarious and thus occur in more dense populations. Therefore, the minimum area of black-tailed prairie dog colonies that can support ferrets may be smaller than that for other prairie dog species (Clark, 1994).

We removed patches that were below the minimum size suitable for black-footed ferret survival in each habitat model with the Clump and Eliminate commands in ERDAS IMAGINE. We filtered predicted habitat based on the minimum area suitable for black-footed ferret survival. We used a minimum patch size of 40 ha in the black-tailed prairie dog range, 60 ha in the Gunnison’s prairie dog range, and 80 ha in the white-tailed prairie dog range.

Although the ability of various habitats to support populations of a given size will only be known from the results of reintroductions, at present it appears that large complexes are necessary for viable ferret populations (U.S. Fish and Wildlife Service, 1988). The minimum areas we chose may be reasonable based on available bioenergetic and behavioral information, however, and we offer them as working hypotheses in presenting our methodology for allocating ferret recovery.

Ferret Allocation

The 1988 recovery plan deferred specification of a delisting population size pending outcomes of reintroductions and accumulation of additional management experience (U.S. Fish and Wildlife Service, 1988). We offer a hypothetical delisting population size of 15,000 ferrets, an order of magnitude larger than the downlisting objective specified in the 1988 recovery plan. We chose this value based on several lines of reasoning. First, large prairie dog colonies such as those currently used for reintroductions may be scarce (Dobson and Lyles, 2000). Additional, smaller populations may be necessary to meet any delisting objective. Second, a larger number of smaller populations may help protect against catastrophic events (e.g., disease outbreaks) that can decimate entire populations (Forrest and others, 1988). Third, fossil evidence supports the hypothesis that black-footed ferrets may have been more common throughout the historical range (Linder and others, 1972; Choate and others, 1982; Hubbard and Schmitt, 1984; Anderson and others, 1986).

Although the majority of habitat occurs in the black-tailed prairie dog range, we suggest larger than proportional allocations of black-footed ferrets in the white-tailed and Gunnison’s prairie dog ranges. We suggest 8,625 ferrets (57.5 percent) allocated to the black-tailed prairie dog range; 3,375 ferrets (22.5 percent) to the Gunnison’s prairie dog range; and 3,000 ferrets (20 percent) to the white-tailed prairie dog range. To equitably divide ferret recovery across jurisdictional entities, we calculated the total amount of predicted habitat in the individual prairie dog ranges, calculated the percent of predicted habitat in each State, and then used those percentages to apportion black-footed ferrets by State and by prairie dog species.

Results and Discussion

Black-tailed Prairie Dog

Using the model described above, we calculated about 128.9 million ha of predicted habitat in the black-tailed prairie dog range (table 1), or about 71 percent of the range distribution as described by Hall (1981). The largest amount of predicted habitat occurred in Texas and encompassed over 29.2 million ha. New Mexico provided the second largest amount of predicted habitat with ~16.0 million ha. Nebraska, Kansas, and Montana had similar amounts of predicted habitat, with approximately 14 million ha each. North Dakota and Arizona, both considered range extremes, had the smallest estimate of predicted habitat with ~3.5 million ha and ~1.5 million ha, respectively. Texas was allocated 1,957 individual black-footed ferrets, and New Mexico was allocated 1,072 ferrets. South Dakota, where the last known extant populations of ferrets occurred in the black-tailed prairie dog range, was allocated 746 black-footed ferrets, and Wyoming was

Table 1. Amount of predicted habitat by prairie dog (*Cynomys*) species and jurisdictional entity, and resulting black-footed ferret (*Mustela nigripes*) allocations based on the hypothetical delisting objective of 15,000 individuals.

State	Predicted habitat (ha)	Percent of predicted habitat within each jurisdictional entity	Number of ferrets allocated	Minimum habitat required (ha)	Minimum habitat as a percent of total
Black-tailed prairie dog (*C. ludovicianus*)					
Arizona	1,484,257	1.2	99	3,960	
Colorado	9,870,127	7.7	660	26,400

Total	13,533,251	100.0	3,375	202,500	1.50
White-tailed prairie dog (*C. leucurus*)					
Colorado	934,483	8.9	268	21,440	
Montana	53,308	0.5	15	1,200	
Utah	1,075,817	10.3	309	24,720	
Wyoming	8,394,910	80.3	2,408	192,640	
Total	10,458,518	100.0	3,000	240,000	2.29

allocated 501. The State with the lowest ferret allocation was Arizona.

Based on our calculations (table 1), the minimum amount of habitat needed in the range of the black-tailed prairie dog was about 345,000 ha. Texas, with 23 percent of the predicted habitat, required a minimum of ~78,000 ha, and New Mexico required ~43,000 ha. Arizona could contribute ~4,000 ha. Overall, the minimum amount of habitat needed to achieve the hypothetical delisting objective was less than 1 percent of the total predicted habitat.

The amount of predicted habitat was calculated from input variables based on our model. We recognize that different definitions of suitable land cover could result in different amounts of predicted habitat and different ferret allocations. For example, we included agricultural land in our model based on the recognition that large areas of historically suitable prairie dog habitat were converted to cropland after settlement because prairie dogs prefer deep, relatively level soils—the same land preferred for agricultural development (Choate and others, 1982; Clark, 1986). Although we do not assume that land under current cultivation practices would be converted back to rangeland solely to provide black-footed ferret habitat, some agricultural practices may be compatible with black-footed ferret and prairie dog management, provided that prairie dogs can be tolerated (U.S. Fish and Wildlife Service, 1988). Overall, the agriculture class was approximately 44.7 million ha or 34 percent of the predicted habitat in the black-tailed prairie dog range. Oklahoma and Kansas had the largest proportions of agriculture, with more than 52 percent of the area under cultivation. In New Mexico, agriculture totaled over 48 percent of the area.

Gunnison's Prairie Dog

The amount of predicted habitat in the Gunnison's prairie dog range was over 13.5 million ha or 40 percent of the range distribution as described by Hall (1981). New Mexico had ~5.5 million ha of predicted habitat, followed closely by Arizona with ~5.3 million ha. Colorado had ~2.2 million ha of predicted habitat and Utah ~482,000 ha (table 1).

Based on our calculations, New Mexico and Arizona were allocated a similar number of black-footed ferrets, approximately 1,350 individuals. Colorado and Utah combined were allocated 671 ferrets. Our results indicate that the minimum amount of habitat needed to achieve the hypothetical ferret recovery goal was 1.5 percent of the total predicted habitat in the Gunnison's prairie dog range.

Unlike the black-tailed prairie dog range, inclusion of the agriculture land cover class did not have much impact in the Gunnison's prairie dog range. Only 5 percent of the area was estimated to be in agriculture; however, additional information, as it becomes available at a regional scale, might improve the model. For example, soil type, soil depth, and rock ground cover are important variables in defining Gunnison's prairie dog habitat (Wagner and Drickamer, 2004). These variables should be included in the model when the spatial data become available.

White-tailed Prairie Dog

White-tailed prairie dogs afforded the least amount of predicted habitat, ~10.5 million ha or 45 percent of the range distribution as described by Hall (1981). The majority of predicted habitat in the white-tailed prairie dog range occurred in Wyoming, which had over 8.3 million ha. Montana was estimated to have less than 1 percent of the total predicted habitat (table 1).

Based on our estimates (table 1), Wyoming could host 2,408 black-footed ferrets, Utah 309, Colorado 268, and Montana 15. Overall, in the white-tailed prairie dog range, the minimum amount of habitat needed to reach the hypothetical black-footed ferret recovery goal was 240,000 ha, with Wyoming contributing most of the potential habitat. The minimum amount of habitat estimated to achieve our hypothetical delisting objective was 2.3 percent of the total predicted available habitat.

As with the Gunnison's prairie dog predicted model, inclusion of agriculture did not strongly affect the outcome for white-tailed prairie dogs, with only 7 percent of the area classified in the agriculture land cover type; however, the white-tailed prairie dog model could be improved with more detailed land cover information. For example, the NLCD shrubland cover class may be too general to define white-tailed prairie dog habitat. Although white-tailed prairie dogs occur in shrubland habitats, shrub height and density (Collins and Lichvar, 1986) may be better predictive variables.

Distribution of Resources

Based on our model, Wyoming received the largest allocation of black-footed ferrets with approximately 2,909 individuals. New Mexico was allocated 2,445 individuals and Texas 1,957. The total amount of predicted habitat across all prairie dog species was 152.9 million ha. We calculated a minimum of 787,500 ha of habitat needed to attain the hypothetical delisting of the black-footed ferret, or less than 1 percent of the potential available habitat. Our results support the conclusion in the 1988 recovery plan that sufficient habitat to meet downlisting is less than 0.1 percent (75,000–100,000 ha) of western rangelands (U.S. Fish and Wildlife Service, 1988).

Conclusion

Our technique has several underlying assumptions. The principal assumption is that all prairie dog habitat is suitable black-footed ferret habitat. We recognize that black-footed ferret habitat is more restricted, requiring complex spatial configurations of prairie dog colonies, specific distances between those colonies, and substantial prairie dog densities (Stromberg and others, 1983; Houston and others, 1986; Biggins, Lockhart, and Godbey, this volume). Another assumption of our technique is that land cover data identified from modern remote sensing platforms can reasonably predict prairie dog habitat. Nevertheless, we offer this technique as a test case and encourage modifications and refinements. Future efforts should consider using a larger variety of input variables with more locally specific information, different classifications of land cover or slope categories, and greater spatial resolution.

Our technique (or refinements of it) could be used to allocate black-footed ferret recovery across jurisdictional entities. This technique may help place long-term black-footed ferret recovery into a national scope based on equitable contributions among those entities. In so doing we hope to inspire creative thinking on how specific recovery goals might be allocated across the historical range. We hope to motivate the collaborative effort among Federal and State agencies, conservation groups, and private landowners that will be needed to turn the black-footed ferret back from the brink of extinction (Cole, 1989; Reading and Miller, 1994).

Acknowledgments

We are indebted to T. Schrader for his computer expertise and configuration of hardware and software, which enabled manipulation of our large digital data sets. Special thanks to K. Young for his constructive review of the manuscript. Financial assistance for this project was provided by the South Dakota Ecological Services Field Office of the U.S. Fish and Wildlife Service. The New Mexico Cooperative Fish and Wildlife Research Unit at New Mexico State University provided access to GIS software.

Habitat Restoration and Management

By Joe C. Truett,[1] Kristy Bly-Honness,[2] Dustin H. Long,[3] and Michael K. Phillips[4]

Abstract

Black-footed ferrets (*Mustela nigripes*) historically occupied colonies of three prairie dog (*Cynomys*) species—Gunnison's (*C. gunnisoni*), white-tailed (*C. leucurus*), and black-tailed (*C. ludovicianus*)—more or less throughout their ranges. Historical declines in the abundance of ferret habitat (prairie dog colonies) resulted from poisoning of prairie dogs, sylvatic plague, conversion of habitat to agriculture, and changes in grazing practices to benefit mid-height and tall grasses. Prairie dog restoration often involves translocating prairie dogs into vacant habitat and managing vegetation to enhance colony growth. Sites for reestablishment should be selected with attention to ecological suitability, level of plague risk, return on economic investment in restoration and management, and social acceptability. Plague, conventional grazing and farming practices, and hostility of land managers toward prairie dogs can depress rates of restoration, but incentives may help overcome these obstacles. Two case histories illustrate restoration and management of black-tailed prairie dogs in two grassland types—mixed-grass and shortgrass. Options for expanding ferret habitat restoration and management opportunities include using small prairie dog complexes for ferret releases, introducing more intensive grazing to benefit black-tailed prairie dogs in taller grasslands, and reclaiming retired farmlands with shortgrass species beneficial to prairie dogs.

Keywords: black-footed ferret, *Cynomys* spp., habitat, management, *Mustela nigripes*, prairie dog, restoration

Introduction

Black-footed ferrets (*Mustela nigripes*) require populations of prairie dogs (*Cynomys* spp.) for sustained existence in the wild. Historical distribution records of ferrets coincide closely (though not exactly) with the presence of prairie dog colonies and the known historical ranges of three prairie dog species—black-tailed (*C. ludovicianus*), white-tailed (*C. leucurus*), and Gunnison's (*C. gunnisoni*). Ferrets collected outside prairie dog colonies or ranges could have come from ferret populations within colonies (Hubbard and Schmitt, 1984; Anderson and others, 1986). Efforts to recover ferrets proceed under the assumption that wild populations cannot long survive without prairie dogs (U.S. Fish and Wildlife Service, 1988).

Ferret habitat restoration thus implies restoration and management of prairie dogs, which of course requires suitable prairie dog habitat. Many landscapes historically occupied by black-tailed, white-tailed, or Gunnison's prairie dogs have been changed by conversion to agriculture, alterations in large herbivore abundance, or increases in woody vegetation. Singly or in combination, these changes have altered habitat suitability for prairie dogs (U.S. Fish and Wildlife Service, 2000; Knowles, 2002). Thus, habitat restoration for ferrets often must begin with habitat restoration and management for prairie dogs.

We focus herein on restoration and management of prairie dogs as a means of restoring ferret populations. First we discuss historical patterns of ferret and prairie dog abundance and, partly on that basis, regional priorities for restoration. Then we describe prairie dog restoration and management methods, challenges to both, and ways of expanding opportunities. Some issues, such as relative habitat quality among the prairie dog species, the influences of plague and predation, and the effects of livestock grazing, also are addressed elsewhere in this volume.

Ferret Habitat: A Historical Perspective

Historical information on ferret habitat is limited because of the fossorial and nocturnal habits of the species (Biggins and Schroeder, 1988) and its early demise. Even so, making the most of available data seems imperative; such data not only provide a rough template for restoration but also can inform the recovery process. The most reliable data primarily include past distributional abundance of ferrets based on verified records (usually collections) and the biogeographical patterns that can be inferred from these records. We recognize that collection records provide a poor surrogate for ferret abundance (numerous factors could influence collection density, as discussed later), but few other historical data sets are as relevant to restoration.

The general picture that emerges from verified records shows a ferret distributional range largely overlapping the ranges of the three prairie dog species (fig. 1). Black-tailed prairie dog range, being much more extensive than ranges of white-tailed and Gunnison's prairie dogs, encompasses most of the ferret range and accounts for most of the ferret records (Powell, 1982; Anderson and others, 1986). An important question for restoration is whether these records suggest any apparent preferences of ferrets for prairie dog species or biogeographic regions.

If one assumes that density (number per unit area) of ferrets collected or otherwise verified in prairie dog range correlates with habitat quality or preference, Anderson and others' (1986) distribution maps in most cases suggest no clear preference among species within the same regions. Other factors, however, such as proportion of prairie dog range occupied by colonies, could confound judgments of habitat quality based solely on ferret records. Biggins, Lockhart, and Godbey (this volume) and Ernst and others (this volume) note the likelihood that higher density populations of prairie dogs supported more ferrets per unit area, and, as Knowles (2002) indicated, black-tailed prairie dogs usually occur in higher densities than do the other two species. New Mexico presents a conundrum (see also below) in that about four times as many ferret records came from Gunnison's as from black-tailed prairie dog range in the State (Anderson and others, 1986) despite the probable greater density of black-tailed prairie dogs and the estimated similarity in area occupied by the two species (see Hubbard and Schmitt, 1984).

The distribution of ferret records in black-tailed prairie dog range suggests that a greater density of ferrets occurred in northern parts than in southern parts. The northern half of the range produced about eight times as many ferret records as did the southern half (calculated from Anderson and others [1986]; fig. 1). Furthermore, numbers of ferret records from Montana, Texas, and the portion of New Mexico occupied by black-tailed prairie dogs (Anderson and others, 1986), viewed in light of estimated prairie dog colony area (table 1), show ferret records per habitat unit in Montana to be about 50 times those in New Mexico and well over 100 times those in Texas. Bailey (1905) described a single colony of black-tailed prairie dogs in Texas that occupied about 65,000 km^2; Anderson and others (1986) showed only two to five ferrets verified from the region occupied by that colony. In comparison, South Dakota's entire prairie dog range (including the unoccupied parts) covered only about twice that area but yielded 99 ferret records. Oklahoma, a southern State with roughly the same area of prairie dog range as that of South Dakota, yielded only four ferret records (Anderson and others, 1986).

Several factors other than habitat quality could have contributed to these north-south differences. Flath and Clark (1986) may have substantially underestimated the area of prairie dog colonies in Montana, and Bailey (1905) may have substantially overestimated it in Texas (D. Gober, oral commun., 2003). Trapping for furs, which accounted for some of the specimens collected (Anderson and others, 1986), may have been more intensive in areas producing better furs—that is, northern regions. The intrusion of agriculture into eastern portions of black-tailed prairie dog range may have occurred earlier in southern than in northern States, perhaps biasing

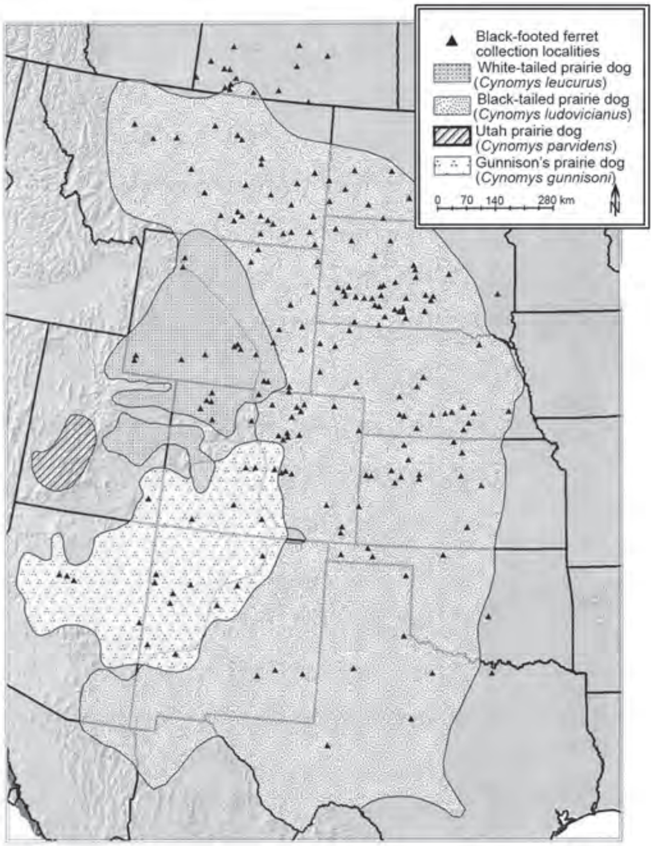

Figure 1. Collection locations for black-footed ferrets (*Mustela nigripes*) (Anderson and others, 1986) and historical ranges of prairie dogs (*Cynomys* spp.) across the Great Plains. Each collection location (dark triangle) represents $\geq$1 verified historical record(s).

Table 1. Black-footed ferret (*Mustela nigripes*) collection records from black-tailed prairie dog (*Cynomys ludovicianus*) range in three states, and densities of records within ferret habitat based on reported habitat acreages (i.e., areas occupied by prairie dog colonies).

State	Number of ferret records[a]	Estimated area (km^2) of habitat available	Ferret records/ 100 km^2 of habitat
Montana	44	6,000[b]	0.733
Texas	13	230,000[c]	0.006
New Mexico	3	~21,000[d]	0.014

[d] Hubbard and Schmitt (1984).

later collection efforts toward northern States (Anderson and others, 1986). Finally, far southwestern (Chihuahuan Desert) portions of black-tailed range, having historically lacked large wild grazers (Truett, 1996), may have supported low numbers of prairie dogs (and few or no ferrets) prior to the proliferation of cattle (*Bos taurus*) (Hubbard and Schmitt, 1984).

Definitive answers about latitudinal differences in habitat quality of black-tailed prairie dog colonies will come only with comparisons between ferret releases that span the historical range. To date, colony complexes near Janos, Chihuahua, Mexico, host the only ferret releases in southern parts of black-tailed prairie dog range. The youth of this release program precludes a reliable assessment of its success.

Regional Priorities for Restoration

The Black-footed Ferret Recovery Plan (U.S. Fish and Wildlife Service, 1988) calls for establishing the widest possible distribution of 10 or more self-sustaining ferret populations. Sites for release of ferrets are selected on the basis of several criteria of habitat suitability (Biggins and others, 1993), key among which are size and expected longevity of prairie dog colony complexes. To complement this strategy, those planning prairie dog restorations probably should set regional priorities. We believe that important criteria for setting such priorities include level of plague risk, species of prairie dog, and regional differences in habitat quality within prairie dog species. All of these criteria will affect relative costs of prairie dog restoration and management.

Plague Risk

The sensitivities of prairie dogs and ferrets to plague make it the most important long-term threat to ferret habitat restoration in regions susceptible to epizootics. The historical spread of sylvatic plague eastward from the west coast and the apparent termination of this advance at the so-called plague line are addressed elsewhere (Cully and Williams, 2001; Gage and Kosoy, this volume). At present, plague apparently occurs in the wild more or less throughout the ranges of white-tailed and Gunnison's prairie dogs and in black-tailed range to about the western borders of South Dakota, Nebraska, Kansas, and Oklahoma—the plague line (Cully and Williams, 2001). The chances of plague epizootics affecting prairie dogs and ferrets west of the plague line seem to vary considerably among localities and to diminish as one nears the line.

Prairie Dog Species

Available evidence suggests to us that, among prairie dog species, the Gunnison's ranks lowest in priority for ferret habitat restoration and that the black-tailed ranks highest. We rank the Gunnison's prairie dog lowest primarily because of the species' relatively high and persisting losses rangewide to plague (Cully and Williams, 2001; Knowles, 2002) and its relatively intact (unaltered) habitat (Knowles, 2002); these factors suggest that restoration and habitat management efforts may lead to little long-term improvement in population status of the species. The average low survival and reproduction of ferrets released into a large Gunnison's prairie dog complex in Arizona (Conservation Breeding Specialist Group, 2004) suggest that, for unclear reasons, ferret habitat quality may be poor (plague appears to be absent at release sites).

We rank the white-tailed prairie dog second in priority. Although also at high risk from plague rangewide, this species is believed to suffer lower losses to epizootics than do Gunnison's or black-tailed prairie dogs, perhaps because of its commonly low population densities (Menkens and Anderson, 1991; Cully and Williams, 2001). In support of this belief, releases of ferrets during 1991–94 into a white-tailed prairie dog complex in Wyoming's Shirley Basin (Luce and others, 1997) resulted in unexpectedly high numbers of ferrets present in 2003 (Grenier, 2003), despite plague epizootics in the interim (Luce and others, 1997; Cully and Williams, 2001). Like Gunnison's prairie dogs, however, white-tails probably offer low per capita returns on investment in restoration and habitat management because of their low density and relatively intact habitat (Knowles, 2002).

We rank the black-tailed prairie dog highest in priority. A substantial proportion of their relatively large range remains plague free, densities within colonies (especially in plague-free areas) tend to be relatively high, and restoration and management efforts can yield high per capita returns. Much of the habitat within their historical range has been degraded, but substantial proportions could be restored. The most successful releases of ferrets have been in plague-free parts of black-tailed prairie dog range (Conservation Breeding Specialist Group, 2004).

Regions Within Black-tailed Prairie Dog Range

Priority for restoration varies from place to place within black-tailed prairie dog range. Most obviously, priority increases with decreased risk of plague. Ferrets released east of the plague line in South Dakota have survived and reproduced much better than those released west of the plague line in Montana (Conservation Breeding Specialist Group, 2004). Also, as noted above, if distributional abundance of ferret records correlates with habitat quality, restoration priority increases with latitude.

Restoration Methods and Challenges

We discuss two aspects of prairie dog restoration: reestablishment of populations and habitat improvement. Hostile traditions toward prairie dogs among land managers represent an important socioeconomic challenge to prairie dog restoration; incentives may help address this challenge.

Translocation

Timely restoration will require reestablishing prairie dogs where they formerly existed. At least three factors will hinder natural recolonization: (1) large spatial vacancies within previously occupied ranges, (2) short dispersal distances of black-tailed prairie dogs (Knowles, 1985) and probably the other species as well, and (3) infrequency with which new colonies originate on their own (Knowles, 1982). Translocations to establish new colonies will greatly accelerate the rate of restoration (D. Long and K. Bly-Honness, unpub. data, 2004).

Unlike natural colonization, translocation can space colonies across landscapes to form complexes ideal for ferrets and compatible with other land uses (see Bevers and others, 1997; Hof and others, 2002). Because small, new colonies expand much faster than large, old ones (Knowles, 1982; D. Long and K. Bly-Honness, unpub. data, 2004), translocation accelerates the rate of population growth. Also, translocation can retard or control unwanted expansion in source colonies by removing substantial proportions of the populations.

Only Utah prairie dogs (*C. parvidens*) and black-tailed prairie dogs have been extensively translocated (Truett and others, 2001a). Translocations of Utah prairie dogs commenced in the early 1970s with concern for the imperiled status of that species. Large-scale translocations of black-tailed prairie dogs have taken place primarily since 1990 (Long and others, in press). Methodologies for both species have been published elsewhere; below we review and compare these methods and recommend approaches that seem to work best for ferret habitat restoration.

Black-tailed Prairie Dogs

Source populations for translocating black-tailed prairie dogs should be selected with attention to disease risks, potential legal restrictions, genetic makeup, and effect of removal on the source population (Truett and others, 2001a; Long and others, in press). To date, plague presents the greatest disease problem and may indicate the need to quarantine animals (Marinari and Williams, 1998) before release. Monkeypox is an emerging disease issue but so far is confined to captive prairie dogs and other rodents. State or Federal restrictions on trapping and transporting prairie dogs may exist; recent restrictions related to monkeypox (U.S. Department of Health and Human Services, 2003) are the most prohibitive to date in that they restrict trapping and transport of all prairie dogs without special exemption. With respect to maintenance of unique gene pools, some biologists have voiced concern about translocating prairie dogs long distances. In practice this concern has influenced few translocation programs, although in New Mexico we acquired prairie dogs from a specific locality to help preserve the gene pool. Using translocations to remove unwanted animals is an attractive idea but in fact is an inefficient and often ineffective control method, in part because most populations seem able to support sustained harvests of at least 25–30 percent annually (T. Livieri, unpub. data, 2002).

The best sites for releases often have evidence of previous occupancy, but risk of plague or encroachment of tall vegetation may have degraded the suitability of such sites (Long and others, in press). Sites without evidence of historical occupancy also can be suitable if soils are deep and relatively fine textured and slopes are less than about 6 percent (Reading and Matchett, 1997). Grass dominance by grazing-resistant species is an important indicator of release site suitability (Long and others, in press).

Operators capture prairie dogs for translocation usually with livetraps but sometimes by pulling them from burrows with a vacuum truck or flushing them out with water (Truett and others, 2001a; Long and others, in press). We advise immediately treating captured animals with a pesticide to kill fleas, which can transmit plague, and then transporting them in wire-mesh cages to quarantine facilities or release sites. Important protocols for handling captive prairie dogs include protection from extreme temperatures, provision of adequate food and water, euthanization if seriously injured, and necropsy of any dying from unknown causes (Marinari and Williams, 1998).

We and most other practitioners conduct translocations during July–September to reduce losses of the very young that would occur with translocations in spring and to give released animals time to excavate new burrows before winter (Long and others, in press). We (Truett and others, 2001a; Long and others, in press) mow tall vegetation at release sites to 10 cm or less and hold the prairie dogs there for several days in acclimation cages consisting of belowground nest boxes connected by an access tube to aboveground retention baskets. The acclimation cages contribute greatly to survival by reducing dispersal and providing shelter from predators during the first few months postrelease while the prairie dogs are excavating new burrows. Predation by coyotes (*Canis latrans*) and badgers (*Taxidea taxus*) during this period usually accounts for most of the postrelease losses; installation of nest boxes at least 1.2 m deep, monitoring for predators at release sites for 2–3 weeks, and selective control of predators during this time commonly result in 50 percent or more surviving onsite at the end of 2 months. By that time, loss rates decline substantially. We usually see recruitment of young at near normal rates the following May and June.

In our experience, most operators translocate prairie dogs in groups as trapped without trying to retain them in original family units or specific sex and age groups. We found no significant difference in postrelease survival or recruitment between groups of prairie dogs translocated as family units ($n = 4$) and those translocated as mixed-family groups ($n = 6$) (Bly-Honness and others, 2004), but Shier (2004) found that five groups she translocated as family units survived and reproduced at higher rates than did five groups trapped without attention to family unity. We found (insignificantly) greater average survival among mixed-family groups translocated after being quarantined together for 2 weeks than among those not quarantined (Bly-Honness and others, 2004). Preliminary data indicated lower survival in groups containing more than about 60 percent juveniles than in groups containing less than about 40 percent juveniles (K. Bly-Honness and D. Long, unpub. data, 2004).

After several months, released animals have usually excavated numerous new secure burrows, and control of depredating coyotes and badgers becomes less important. Occasionally, large losses of prairie dogs at a release site will necessitate supplemental releases during the first several months after the initial release. Supplements usually survive at higher rates than those originally released because they take advantage of the burrows excavated by the first contingent. After several months to a year, management of colonies established by translocation differs little from management of preexisting colonies.

Other Prairie Dog Species

The relatively extensive work on translocation of Utah prairie dogs may instruct efforts to translocate white-tailed and Gunnison's prairie dogs. Utah prairie dogs are more closely related to these two species than are black-tailed prairie dogs, and they occupy similar habitats (i.e., intermountain valleys, benches, and plateaus; Knowles, 2002). Utah prairie dogs were first translocated in 1972, and approximately 20,000 individuals have been moved to date (Long and others, in press). In this section we focus on aspects of these translocations that are different from those discussed above for black-tailed prairie dogs. These differences are rather minor; they include primarily release-site selection and preparation and postrelease protection and monitoring.

Coffeen and Pederson (1993), citing Crocker-Bedford and Spillett (1981), provided criteria for release-site selection for Utah prairie dogs. Sites should be well drained, with soils at least 1.2 m deep and not easily collapsible. Vegetation should be sufficiently short or sparse to allow good horizontal visibility but sufficiently lush to provide forage even in dry periods. Evidence of previous occupancy by prairie dogs increases a site's suitability rating.

Treatment of release sites for Utah prairie dogs has primarily involved removal of tall, dense vegetation and augering of artificial burrows. Player and Urness (1982) demonstrated the benefits of shrub removal to postrelease survival; removal of plants that obstruct horizontal visibility has become standard practice (McDonald, 1993). Augered holes 9–15 cm in diameter and 0.5–1.0 m deep at angles into the ground provide relief from temperature extremes and some level of protection from predators (Player and Urness, 1982; Jacquart and others, 1986; McDonald, 1993). Covering entrances of augered holes with wire-mesh retention baskets to temporarily restrain the prairie dogs and acclimate them to the site (Player and Urness, 1982; Jacquart and others, 1986) appears to improve postrelease survival (McDonald, 1993).

As with black-tailed prairie dogs, mammalian predators, particularly badgers, apparently have caused the greatest losses in translocated Utah prairie dogs (Jacquart and others, 1986; Coffeen and Pederson, 1993; McDonald, 1993). Badger damage has been greatest during the first year or two following release, before the prairie dogs have excavated many secure burrow systems (Jacquart and others, 1986). In comparison, black-tailed prairie dogs usually seem secure from extensive badger depredation after several months (see above). Postrelease monitoring for predators and selective control of badgers are commonly used to protect Utah prairie dogs at release sites (Jacquart and others, 1986; Coffeen and Pederson, 1993). Even so, loss of released animals to badger predation remains a major problem (McDonald, 1993; D. Biggins, written commun., 2003).

Vegetation Management

For several reasons we address primarily black-tailed prairie dogs in this section. This species has a larger historical range that has been proportionately more degraded by agriculture and vegetation change than is the case with white-tailed and Gunnison's prairie dogs (Knowles, 2002). Absence of plague in substantial portions of black-tailed range, coupled with greater average densities of the species, increases the unit-area benefits of habitat restoration. Further, more information exists about habitat restoration and management for black-tailed than for white-tailed or Gunnison's prairie dogs, although the scarcity of information on the latter can be partly offset by the relatively rich database for the Utah prairie dog.

Prairie dogs respond markedly to habitat structure—soil texture, slope, and particularly vegetation height and density (Slobodchikoff and others, 1988; Reading and Matchett, 1997; Truett and others, 2001a). Short vegetation benefits all three species (Longhurst, 1944; Knowles, 1982; Slobodchikoff and others, 1988), presumably because it facilitates visual detection of approaching predators. Black-tailed prairie dogs seem more adversely affected by tall, thick vegetation than do Gunnison's or white-tailed prairie dogs (Scheffer, 1947; Hoogland, 1981; Hubbard and Schmitt, 1984). This effect may be a consequence in part of interspecific differences in predator avoidance behavior (Hoogland, 1981). Detection of predators by visual cues and intraspecific warning calls seem more highly developed in black-tailed prairie dogs, as does clipping of vegetation to improve visibility (Tileston and Lechleitner, 1966; Hoogland, 1996). These characteristics of this species may be evolutionary adaptations to exploit heavily grazed landscapes (Truett, 2003).

Many have noted the positive response of black-tailed prairie dogs to intensive grazing by large herbivores. Osborn and Allan (1949), Snell and Hlavachick (1980), Knowles (1982, 1986), and Cable and Timm (1988) documented expansion of colonies with heavy grazing and their stabilization or shrinkage without grazing in areas supporting mid-height or tall grasses. Truett and others (2001b) and Truett (2003) discussed historical fluctuations in abundance of black-tailed prairie dogs in Great Plains grasslands as a function of changing abundance of large grazers. Other ways of keeping the vegetation short, such as burning or mowing, can substitute for grazing (Ford and others, in press).

Only in shortgrass steppe, which occupies a relatively small part of their historical range (compare fig. 1 with fig. 2), do black-tailed prairie dogs seem relatively free of the need for large grazers (D. Long, unpub. data, 2004). In mixed-grass and tallgrass prairie, sustained absence of grazing (Osborn and Allan, 1949; Knowles, 1982), or simply grazing deferment during the growing season (Snell and Hlavachick, 1980; Snell, 1985), can within a few years or decades exclude black-tailed prairie dogs. This may hold true as well in many historically occupied sites in Chihuahuan Desert grasslands (Truett and Savage, 1998; J. Truett, unpub. data, 2004).

White-tailed, Gunnison's, and Utah prairie dogs tolerate tall, dense vegetation better than do black-tailed prairie dogs. Hoogland (1981) noted the relatively large numbers of shrubs in white-tailed prairie dog colonies (compared with black-tailed colonies) and thought they might serve as protective cover. Taylor and Loftfield (1924) and Longhurst (1944) noted the tolerance of Gunnison's prairie dogs for tall grasses and shrubs in their colonies. Collier and Spillett (1975) and Coffeen and Pederson (1993) indicated that Utah prairie dogs often coexist with, and may benefit from, shrubs.

Still, habitat quality for these species often appears to decline with increasing shrub density beyond some point. Longhurst (1944) described increasing density of Gunnison's prairie dogs with decreasing shrub density and increasing visibility. Collier and Spillett (1975) and the U.S. Fish and Wildlife Service (1991) attributed declines of Utah prairie dogs partly to historical increases in shrub density. As with black-tailed prairie dogs, these species may continue to face declining habitat quality unless tall vegetation (shrubs in this case) can be controlled. The federally threatened status of the Utah prairie dog has prompted attempts at habitat rehabilitation by "chopping" (Coffeen and Pederson, 1993), "rotobeating," "railing," and burning (Player and Urness, 1982) shrubs. Similar efforts to improve habitat for white-tailed and Gunnison's prairie dogs have not been reported.

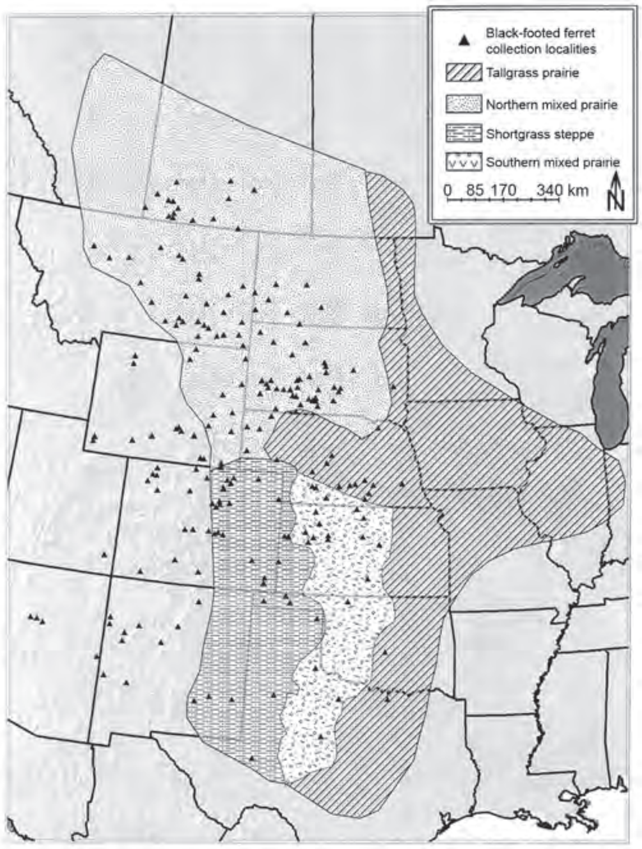

Figure 2. Collection locations for black-footed ferrets (*Mustela nigripes*) (Anderson and others, 1986) and distribution of Great Plains grassland types (Lauenroth and others, 1999). Each collection location (dark triangle) represents $\geq$1 verified historical record(s).

Socioeconomic Challenges

Aside from plague, the greatest impediment to prairie dog restoration may be hostile traditions among rangeland owners and managers. The historical demise of prairie dogs resulted in large part from control programs aimed at removing a presumed competitor with livestock (Merriam, 1902; Mulhern and Knowles, 1997). Perceptions molded by a century of institutionalized control of prairie dogs (Reading and others, 1999) will be difficult to reverse. To exacerbate the dilemma, livestock production on rangelands has long built on the tradition of moderate grazing uniformly distributed (Fuhlendorf and Engle, 2001), which, especially in mixed-grass and tallgrass prairie, militates against rapid restoration (Truett, 2003).

At a recent symposium on black-tailed prairie dogs, a Colorado rancher was asked why ranchers dislike prairie dogs. In response, he largely dismissed the risk of cattle breaking their legs in burrow entrances but pointed to the loss of forage that could reduce profits. Then, after some hesitation, he offered another important insight—prairie dog colonies simply look bad. Who wants to see his land blighted by the disturbed soil and rodent activity characteristic of prairie dog colonies? In word and gesture he portrayed prairie dogs as symbols of neglect, pariahs of the range, their presence a sign of lax stewardship comparable to an untidy house at Sunday dinner.

Independent of prairie dog control, grazing at light to moderate intensities has come to symbolize good land stewardship among range managers. To many, heavy grazing equates with "overgrazing" and unwise use. This perception took root in the early 1900s with Clements' (1916, 1936) model of "proper" grazing as that which maintained grasslands near climax condition (i.e., dominated by the tallest of the species at a given site). Historical evidence indicates that black-tailed prairie dogs thrived over the moister parts of their original range because of heavy grazing, first by bison (*Bison bison*) and then by cattle (Truett, 2003). Unfortunately for ferret restoration, the relatively moist and plague-free areas in the Great Plains that can support the greatest densities of prairie dogs need the heaviest grazing. Thus, black-tailed prairie dog restoration is squeezed between plague risks from the west and "good" range management from the east.

Managers' preferences for tall grass compromise another potentially fruitful avenue for prairie dog habitat restoration—reclamation of abandoned farmland (discussed later). The traditional maxim that tall grass is better grass leads most managers to recommend and use seed mixes containing largely tall or mid-height grass species for reclaiming lands such as those under the Conservation Reserve Program (CRP) of the 1985 Food Security Act.

In sum, those in the best position to restore prairie dogs on private and public lands usually lack the motivation to do so. They often come from rural backgrounds, which predisposes them to dislike prairie dogs (Reading and others, 1999). They subscribe to rural traditions that for generations have seen prairie dogs, and the range conditions associated with them, as economically and socially undesirable.

Given the entrenched nature of tradition, must changes in attitude await a new generation of managers with different cultural backgrounds? Perhaps not. For one thing, recent paradigm changes among professionals about what constitutes good conditions on rangelands (discussed later) may legitimize heavy grazing for conservation purposes (Task Group on Unity in Concepts and Terminology, 1995). A more immediate hope builds around incentives, particularly economic ones. Money has a history of reshaping tradition.

Incentives

Landowners, land managers, and agencies that set land management policy potentially can be motivated to restore prairie dogs through at least three kinds of incentives. The most direct and immediately effective incentive is probably economic—money offered to induce change. Regulation or the threat thereof can be brought to bear through the Endangered Species Act (ESA) or other legal means but may generate resentment and thus delay response. Self-motivated cultural change through education is slower still but usually longer lasting. Long-term success in prairie dog restoration may require a combination of all three strategies.

Economic incentives can come from private or public sources, and we can attest to the effectiveness of both. Turner Enterprises, Inc., and the Turner Endangered Species Fund (TESF) have supported prairie dog restoration on private ranches since 1995. Funding from TESF enabled restoration of prairie dog populations on six ranches and also promoted the concept of prairie dog restoration through educational efforts: technical publications, presentations at symposia and meetings, support of university graduate student programs, and field tours to educate people from grade schoolers through governors. Recently TESF funding has been supplemented by matching funds from nongovernment organizations (e.g., National Fish and Wildlife Foundation) and Federal agencies (e.g., U.S. Fish and Wildlife Service Private Stewardship Grants Program, or PSGP). The PSGP awarded grants for prairie dog restoration to other private landowners as well. In 2005, TESF received additional support through the new federally funded State Wildlife Grants Program as matching funds to assist with prairie dog restoration in South Dakota.

The U.S. Fish and Wildlife Service (2000) recently determined that the black-tailed prairie dog was warranted for listing as threatened under the ESA, listing being temporarily precluded by higher priority actions. This finding stimulated the States included in the species' historical range to collaborate on a conservation strategy (Luce and others, 2001). This strategy has involved a variety of actions including periodic meetings, interagency memoranda of understanding, and agreements on implementation schedules. Fear that management of the species would be assumed by the Federal government motivated this collaboration. The States organized working groups dedicated in part to planning and carrying out restoration actions, and many have completed population estimates and status assessments as a first step toward conservation (Luce and others, 2001). It is too early to assess the extent to which restoration on the ground will result from this action by the Federal government.

Over the longer term, the success of prairie dog and ferret restoration will rely on cultural acceptance of these species as valuable and appropriate components of grassland ecosystems. Private charities, Federal grants, and even government regulations that promote restoration all arose from cultural beliefs that more of nature should be preserved than just the parts generating income. All of these sources of support can disappear without consistent reinforcement of such beliefs. Maintenance of culture-based incentives will require a continuing effort to educate people about the intangible benefits of prairie dogs and other species that have little immediate economic worth. The most enduring incentives are likely to come through intergenerational transmission of values beyond money.

Case Histories

For several years the TESF has been restoring black-tailed prairie dogs on private ranches with the intent of eventually releasing ferrets into the habitat developed. Here we summarize restoration and management efforts on two of these ranches—Vermejo Park Ranch (Vermejo) in shortgrass prairie southwest of Raton, N. Mex., and the Bad River Ranches (Bad River) in mixed-grass prairie west of Pierre, S. Dak. Bison graze both ranches at generally moderate intensities.

Translocations to establish new colonies and protection of prairie dogs from poisoning and shooting have been key to restoration on both ranches. Most releases used source stock from within the respective ranches. Translocation methods followed Long and others (in press). Translocated animals were held for several days prior to release in acclimation cages at the release site; these cages had artificial underground nest chambers that prairie dogs continued to use after release while they excavated new burrows nearby. Predator control focused primarily on coyotes (both ranches) and badgers (Vermejo) during and for a few months following the translocation period. Major field efforts took place during May–October, involving one person on each ranch, with temporary help from another person for 2–3 months during June–August.

Vermejo

Annual monitoring of colony numbers and sizes commenced in 1997. Translocations began in 1999, and from then until 2003 we established 35 new colonies. Two colonies or fewer originated naturally during the 6-year period 1997–2003. Forty-six colonies currently exist, a few formed by the merging of two colonies that were originally separated.

Total area occupied by colonies increased from 202 ha in 1997 to 980 ha in 2003, expanding an average of 31 percent annually (mean of yearly values). Growth rate varied appreciably among colonies, mostly as a function of colony size. Colonies expanded an average of 12 percent per year during 1998–99 when a few large colonies predominated, but expansion increased to an average of 41 percent per year during 2000–03, during which time many small, new colonies were established by translocation.

The short-statured vegetation never seemed to offer much of an impediment to colony growth. Colony growth during 1999, when precipitation and vegetative growth substantially exceeded average, did not differ from that in 1998, when less rain fell. A major drought in 2001 and 2002 (21.8 cm and 23.9 cm, respectively, of precipitation compared with approximately 36.8 cm annual average) greatly reduced vegetative growth and recruitment of young into the prairie dog population but seemed not to influence areal expansion rate of colonies.

Bad River

Annual monitoring of colony numbers and sizes began in 1999, at which time 35 colonies existed. Translocations began in 2000, and from then until 2003 we established 35 new colonies. Eleven new colonies originated naturally during 1999–2003, mostly during a drought year (2002), and six disappeared during a wet year (2001). Seventy-eight colonies, a few having been formed by the merging of two original colonies, existed by late 2003.

Total colony area increased from 271 ha in 1999 to 584 ha in 2003; the average annual increase (mean of yearly values) was 25 percent. Smaller colonies grew faster than larger ones, but the greatest influence on colony growth resulted not from colony size but from grass height and density as a function of precipitation. In 2001, when rainfall and vegetative growth peaked, total colony area shrank 12 percent; in the drought year of 2002 colony area increased 72 percent.

Grazing by bison during years of average or above-average precipitation strongly influenced colony expansion. Heavily grazed colonies in these circumstances expanded at much greater rates than did colonies grazed lightly or not at all. Successful establishment of new colonies in wet years in the absence of grazing required us to mow release sites in summer, sometimes repeatedly, to enhance visibility and postrelease survival. Colonies in an area intensively managed—by establishment of new colonies, grazing at moderate intensities, and mowing as needed—grew 78 percent during the 2-year period that they were managed. Colonies outside this area grew by 29 percent during the same period.

Comparisons and Implications

Colony area in the shortgrass prairie at Vermejo expanded faster on average than that in the mixed-grass prairie at Bad River, and growth rate varied less among years at Vermejo. Our data suggest, however, that the potential average growth at Bad River with intensive grazing or drought may be substantially greater than that at Vermejo. This higher growth rate, coupled with the nearly threefold greater density of prairie dogs at Bad River (D. Long and K. Bly-Honness, unpub. data, 2004), illustrates the great potential that exists for ferret habitat restoration in taller grass regions of the Great Plains. Even so, it may be difficult to maximize this potential without changes in grazing management philosophy, which we discuss below.

Changing Paradigms, New Opportunities

Habitat scarcity seems a looming bottleneck in ferret restoration. The shortage of large prairie dog complexes suitable for ferret release coupled with the increase in ferrets annually available for release suggests a need to evaluate the use of smaller complexes. At the same time, changing philosophies and economics related to the major land uses in ferret range (i.e., grazing and farming) may open new avenues for habitat restoration and management. Below we assess some of the opportunities presented by these changes.

Minimum Size of Prairie Dog Complexes

Clearly, other factors being equal, larger complexes of prairie dog colonies offer better ferret habitat than do smaller ones. Although a high-density colony of black-tailed prairie dogs as small as 10 ha can in theory (Biggins and others, 1993) and in fact (Hillman and others, 1979) support a family of ferrets in the short term, Biggins and others (1993) recommended a minimum 400-ha colony area to sustain a ferret population. The Conservation Breeding Specialist Group

(2004) estimated that 2,440 ha of high-quality habitat (i.e., black-tailed prairie dog colonies in Conata Basin, S. Dak.) would be needed to support 120 breeding adult ferrets with more than 90 percent probability of persistence over 100 years. Moreover, they recommended development of 4,050-ha complexes to achieve ferret recovery objectives.

Given the current scarcity of large complexes secure from poisoning and plague, however, the Conservation Breeding Specialist Group (2004) also recommended investigating ways to enhance ferret recovery by using small (less than 2,000 ha) complexes. Use of smaller sites could attract collaborators (e.g., States and private landowners) excluded by large minimum-area requirements and quickly open up options spanning the entire historical ferret range. Literally and metaphorically, it could plant the seeds needed to ultimately establish larger complexes of prairie dog colonies and the widest possible distribution of ferrets.

Probabilities of extinction rise as ferret population size declines; thus, maintenance of ferrets in small colony complexes might necessitate periodic reintroductions from elsewhere. Still, this inconvenience might be trivial given the possible rewards—attracting wider public and private support, supplying wild-reared kits for release elsewhere, hosting research to better inform a variety of restoration schemes, and maintaining numerous wild populations as a hedge against regional catastrophe. Furthermore, finding ways to use small complexes could ultimately lead to shifts in grazing and farming philosophies to benefit ferret recovery.

New Directions in Grazing: Beyond Clements' Climax

Recently, members of the Task Group on Unity in Concepts and Terminology (1995) of the Society for Range Management laid to rest the conventional notion that grazing according to Clements (1916, 1936) (i.e., maintenance of grass communities near climax) is the sole gospel of good range management. They envisioned an array of potentially "good" grazing management options depending on management goals. In so doing, they legitimized such previously objectionable ideas as intensive grazing in areas of mixed-grass and tallgrass climax to benefit shortgrass species. In our view this change in perspective opened the door conceptually for extending prairie dog and ferret recovery efforts farther eastward into plague-free terrain.

Most ferret records for the Great Plains came from regions where prairie dog populations depended to some extent on grazing; that is, regions dominated by mixed or tall grasses (fig. 2) Historical accounts suggest that grazing by bison, before their demise in the 19th century, facilitated occupancy of these regions by prairie dogs and ferrets; the need for intensive and frequent grazing increased with distance eastward (reviewed by Truett, 2003). Bison had been eliminated in most Great Plains areas well before most ferret collections were made (cf. Anderson and others, 1986; Isenberg, 2000). Prior to bison extirpation, ferrets not only might have been more abundant in eastern portions of their range than numbers collected indicate, but also might have ranged farther east than ecologists have assumed.

Can intensive grazing (by livestock) be reinstated in these eastern, plague-free areas to pave the way for prairie dogs and ferrets? The historical rebound of prairie dogs in some of these areas following entry of cattle in very large numbers in the last decade or two of the 19th century (Merriam, 1902; Truett, 2003) suggests so. Several key management questions surround such a concept.

1. How far east can prairie dogs potentially thrive? Collection records (Hall, 1981) suggest that prairie dogs historically were common farther east than they generally occur now except under anomalous circumstances (e.g., predator-unfriendly sites such as remnant corners of pivot-irrigated fields or human settlements; Sidle and others, 2001; Truett, 2003). Some colonies established by people in high-rainfall areas east of historical range—for example, Nantucket Island off the coast of Massachusetts (Merriam, 1902) and a site east of Fort Worth, Tex. (Schmidly, 1983)—apparently have thrived. In the relatively cool and moist climate of the late Pleistocene, black-tailed prairie dog range extended substantially east of its historical limits (Goodwin, 1995), possibly because of heavy grazing by the numerous megaherbivores of the time (Truett, 2003). The key to prairie dog survival eastward to the limits of historical range and beyond may simply be short grass.

2. What vegetative changes come with the intensive grazing associated with prairie dog occupancy of mixed-grass and tallgrass sites? Mid-height and tallgrass species decline in dominance, often dramatically, and perennial shortgrasses and annuals increase (Detling, 1998; Truett and others, 2001b). Given availability of propagules, shortgrass species such as buffalograss (*Buchloe dactyloides*), blue grama (*Bouteloua gracilis*), and tumblegrass (*Schedonnardus paniculatus*) increase and often persist in dominance (Archer and others, 1987; Weltzin and others, 1997). Net primary productivity (indicative of forage quantity annually available) typically declines over time, but forage quality increases. Heavy grazing by livestock outside colonies causes similar but usually less dramatic changes (reviewed by Truett and others, 2001b).

3. Would these changes reduce profits from ranching operations? The many variables involved preclude a detailed response, but the short answer is sometimes yes and sometimes no (Detling, 1998; this volume). Prime among the important variables is the proportion

of the landscape occupied by prairie dog colonies. Livestock profits may decline if prairie dog occupancy level is high but may increase if occupancy level is low. For example, Vanderhye (1985) projected substantial benefits to bison at a site in South Dakota where prairie dog colonies occupied only 12 percent of the landscape. Moreover, heavy grazing by cattle to benefit prairie dogs may under some conditions yield greater sustainable profits than would more conventional grazing intensities (Manley and others, 1997; Sims and Gillen, 1999).

Reclaiming Retired Farmland

Large proportions of the plague-free part of the Great Plains have been converted to agriculture; these proportions generally increase with distance eastward and southeastward (Lauenroth and others, 1999). Retirement of farm acreages under programs such as the CRP may offer the potential for prairie dog restoration. Could prairie dogs reoccupy retired farmlands? If so, how should reclamation of such lands proceed?

Black-tailed prairie dogs readily colonize abandoned farmland, often in preference to undisturbed prairie. In Montana, Knowles (1982) found that colonies were disproportionately abundant on previously cultivated lands near abandoned homesteads. In Colorado, Koford (1958) observed that prairie dogs near Fort Collins readily invaded fields under cultivation, and D. Seery (oral commun., 2002) noted that many prairie dog colonies on Rocky Mountain Arsenal National Wildlife Refuge, Colo., occupied long-abandoned fields. In Badlands National Park, S. Dak., Langer (1998) found more and larger prairie dog colonies on long-abandoned farmland than on undisturbed prairie. We observed that prairie dogs near Pierre, S. Dak., quickly invaded land last plowed the previous year.

As expected, cultivated land with tall vegetation repels prairie dogs; land with short or very sparse vegetation attracts them (Koford, 1958). Retired farmland reclaimed with perennial shortgrasses should sustain prairie dogs and, in some circumstances, limit erosion better than if tallgrasses were used in reclamation (see Truett, 2003), the latter a prime goal of the CRP. Mid-height and tall species of grass usually dominate CRP seed mixes (Reynolds and others, 1994; Johnson and Igl, 1995; Patterson and Best, 1996), however, rendering fields reclaimed with such mixes unsuitable for prairie dogs and other shortgrass fauna (e.g., see Kamler and others, 2003). Retired farmlands seem lucrative targets for prairie dog restoration, but seed mixes dominated by shortgrass species would be needed, particularly under programs such as CRP that limit grazing on lands enrolled in the program.

Acknowledgments

We thank the Turner family, particularly R.E. Turner, for their continuing interest in and financial support of prairie dog restoration on Turner-owned ranches and for their commitment to dissemination and publication of scientific information. Turner ranch managers T. Waddell, D. Vackar, T. LeFaive, S. Dobrott, K. Yearout, and J. Hansen assisted with prairie dog restoration efforts. We thank A. Ernst for digitizing maps of prairie dog, ferret, and grassland type distributions.

Black-tailed Prairie Dog Interactions with Other Herbivores: Mediation via Alterations of Vegetation

By James K. Detling[1]

Abstract

Intensive grazing by black-tailed prairie dogs (*Cynomys ludovicianus*) typically reduces graminoid biomass and enhances production and standing crop of less desirable forage species; however, the quality of remaining graminoids is often increased because of higher crude protein concentrations and higher digestibility. Increased forage quality may partially account for why some large grazers such as bison (*Bison bison*), pronghorn (*Antilocapra americana*), and possibly cattle (*Bos taurus*) are attracted to prairie dog colonies as preferred sites to graze. In relatively productive grasslands, grazing and disturbance of tall vegetation by large herbivores apparently allow prairie dogs to expand into areas they might not otherwise occupy. These interactions between prairie dogs and large herbivores do not appear to be as strong in the more arid, less productive shortgrass steppe as in the mixed-grass prairie.

Keywords: bison, cattle, *Cynomys ludovicianus*, forage quality, grazing, plant-animal interactions, pronghorn, trophic interactions

Introduction

At the time that European settlers first migrated westward across North America, prairie dogs (*Cynomys* spp.) occupied vast areas of the Great Plains grasslands. For example, Merriam (1902, p. 258) described a single colony that occupied an area of nearly 65,000 km^2 and contained, by his estimate, 400 million prairie dogs. Much of the area originally inhabited by black-tailed prairie dogs (*C. ludovicianus*) is within the shortgrass and mixed-grass prairies, but they also occupy parts of desert grasslands and shrublands in southern New Mexico and northern Mexico (Hoogland, 1995; Detling, 2006). A large portion of their historical range is now either livestock grazing land or cultivated cropland. Because they can consume or destroy large quantities of forage by clipping, widespread eradication campaigns were mounted during the 20th century to eliminate prairie dogs from much of their original habitat. These campaigns, together with habitat loss and the introduction of bubonic plague into much of their former range, has resulted in an estimated 98 percent reduction in their populations from a century earlier (Miller and others, 1990, 1994). We now know that prairie dogs are important in the maintenance of grassland species diversity and are essential for survival of black-footed ferrets (*Mustela nigripes*) in the wild. Therefore, a number of ecologists and conservation biologists recently have argued for elimination of these eradication campaigns (Miller and others, 1990, 1994; Wuerthner, 1997; Kotliar and others, 1999), which has in turn raised concerns among land managers about how rapidly prairie dog populations might grow, what their effects on grassland vegetation might be, and how this might affect livestock or populations of native grazers.

This paper reviews extant literature pertaining to the above issues with respect to black-tailed prairie dogs. Specifically, I address three questions: (1) How does grazing by prairie dogs affect grassland vegetation? (2) What effects might these changes have on other herbivores? (3) How might grazing by other herbivores affect expansion of prairie dog colonies? Knowing the answers to such questions will enable us to better understand the nature of the habitat used by prairie dogs and associated species such as black-footed ferrets and will assist land managers in assessing some of the consequences of managing for increased area of prairie dog habitat.

Effects of Prairie Dogs on Vegetation

Vegetation Characteristics and Prairie Dog Diets

Most native shortgrass and mixed-grass prairies are dominated by perennial grasses and other graminoids, which may compose as much as 90 percent of the aboveground biomass (Coupland, 1992; Lauenroth and Milchunas, 1992). Although they typically make up a relatively low proportion of the biomass, a diverse group of forbs (i.e., herbaceous dicots) and woody sub-shrubs contribute substantially to overall plant species diversity in most Great Plains grasslands (Sims and others, 1978).

---

[1] Colorado State University, Department of Biology and Natural Resource Ecology Laboratory, Fort Collins, CO 80523.

Prairie dog diets consist largely of native graminoids, and many of the species they consume also compose most of the diets of native and domesticated ungulates (Detling, 2006). For example, on the shortgrass steppe of Colorado (Hansen and Gold, 1977) and the mixed-grass prairie of South Dakota (Uresk, 1984), relatively high-quality forage species such as blue grama (*Bouteloua gracilis*), needleleaf sedge (*Carex eleocharis*), western wheatgrass (*Pascopyrum smithii*), and sand dropseed (*Sporobolus cryptandrus*), all native perennial graminoids, made up about 85 percent of prairie dog diets. In contrast, forbs such as scarlet globemallow (*Sphaeralcea coccinea*) and a sub-shrub, fringed sagewort (*Artemisia frigida*), accounted for the other 15 percent. In addition to consuming vegetation, prairie dogs frequently clip and fell taller vegetation, apparently to enhance predator detection (Hoogland, 1995).

Changes in Plant Cover, Biomass, and Species Composition

As a result of their grazing and clipping behaviors, one of the most striking visual effects that prairie dogs have is a reduction in height of vegetation on their colonies. Where vegetation in uncolonized areas is relatively tall, the visual contrast between colonies and adjacent, uncolonized areas may be substantial. For example, at several mixed-grass prairie sites in South Dakota, vegetation adjacent to prairie dog colonies averaged about 25 cm tall while that on the colonies averaged <10 cm (Archer and others, 1987; Whicker and Detling, 1988a; Russell and Detling, 2003). Another common trend following colonization is a reduction in the amount of standing dead plant biomass relative to live biomass (Coppock and others, 1983a; Detling, 1998). Consequently, prairie dog colonies often appear “greener” than surrounding uncolonized grassland, reminiscent of classical “grazing lawns” (sensu McNaughton, 1984). In drier grasslands with shorter vegetation, such as the shortgrass steppe of eastern Colorado and northern New Mexico, differences in height of vegetation on and off colonies are much less dramatic (Guenther and Detling, 2003), and these colonies may not look greatly different from uncolonized grasslands.

As prairie dog colonies in the northern mixed-grass prairie age following initial colonization of a site, perennial graminoids become weakened by repeated leaf removal and the consequent reduction in their photosynthetic capacity. Not only is shoot biomass of graminoids reduced (Coppock and others, 1983a), but root biomass also declines markedly, particularly in older prairie dog colonies (Ingham and Detling, 1984; Whicker and Detling, 1988b; Detling, 1998). Consequently, over time graminoids lose their competitive dominance and are replaced by forbs and sub-shrubs (Coppock and others, 1983a; Archer and others, 1987). In Badlands National Park, S. Dak., for example, 7 of the 10 most abundant species sampled off prairie dog colonies were graminoids, while 8 or more of the most abundant species on old colonies were forbs (Fahnestock and Detling, 2002). Thus, prairie dog colonies may consist of a variety of vegetation types. Younger parts of colonies are grass dominated and have species composition similar to uncolonized sites but lower biomass and cover. The oldest, most altered parts of colonies are forb dominated and often have little or no graminoid cover or biomass. In addition, as colonies age, the proportion of bare ground tends to increase (Whicker and Detling, 1988b; Russell and Detling, 2003).

Less has been written about vegetation changes following colonization of southern mixed-grass prairie sites. At two >50-year-old colonies in Texas, biomass was only one-third to one-fourth as great on colonies as on uncolonized sites because mid-height grasses had been nearly eliminated (Weltzin and others, 1997a,b). In contrast to northern mixed-grass prairie sites, forb biomass was greater off colonies than on colonies, and biomass of short grasses did not differ significantly on and off colonies.

Available evidence suggests that vegetation is less altered by prairie dogs on the semiarid shortgrass steppe than in mixed-grass prairies. Nevertheless, the general trends appear to be in the same direction as in mixed-grass prairies. For example, in a shortgrass steppe in north-central Colorado, forb cover was greater (5.7 percent) on a colony than off it (3.4 percent), while cover of the dominant grass, blue grama, was lower on the colony (12.2 percent) than off it (19.2 percent) averaged over the growing season (Bonham and Lerwick, 1976). Similarly, Winter and others (2002) reported relatively small differences in vegetation structure and species composition on and off prairie dog colonies in shortgrass steppe in southwestern Kansas and southeastern Colorado. Moreover, bare ground was not significantly greater on colonies than off colonies at the Central Plains Experimental Range in northern Colorado (Guenther and Detling, 2003). These patterns of relatively small effects of prairie dogs on shortgrass steppe vegetation are consistent with the notion that this ecosystem has a long evolutionary history of grazing and is very resistant to heavy grazing (Milchunas and others, 1988), perhaps, in part, a result of the widespread dominance of grazing-resistant blue grama in this grassland type (Lauenroth and Milchunas, 1992).

Changes in Forage Quality

In addition to vegetation changes discussed above, grazing by prairie dogs may alter the phytochemistry and forage quality of plants. One such change involves nitrogen (or crude protein) concentration. In the northern mixed-grass prairie, mean live shoot [N] was 1.3 percent (crude protein = 8.1 percent) in six graminoid species off a prairie dog colony and 1.6 percent (crude protein = 10.0 percent) in the same six species on the colony when averaged over a growing season (Coppock and others, 1983a). Similar trends were observed by Krueger (1986). Moreover, the digestibility of graminoids was greater on prairie dog colonies than on uncolonized areas adjacent to them (Coppock and others, 1983a). Vanderhye's (1985) model results, reviewed by Detling (2006), suggested that changes in forage quality of the magnitude observed on these prairie dog colonies could significantly enhance weight gain of bison (*Bison bison*). Thus, heavy grazing by prairie dogs apparently results in a tradeoff: the quantity of forage species preferred by large grazers declines, but the forage quality of those species is enhanced. Determining the consequences of this quantity-quality tradeoff for cattle (*Bos taurus*) or other large grazers is complicated because the magnitude of the tradeoff likely depends on a variety of factors. These include the type of grassland, length of time a site was inhabited by prairie dogs, past and current management practices, weather conditions, and others. Nevertheless, some simple calculations based on data from a mixed-grass prairie site (Coppock and others, 1983a) might illustrate the approximate magnitude of this tradeoff.

Pringle Valley occupies 120 ha in Wind Cave National Park, S. Dak., and at the time of the study, prairie dogs occupied 36 ha (30 percent) of this valley (table 1). Coppock and others (1983a) recognized three zones within the colony based on length of time colonized: old colony (occupied >26 years), young colony (3–8 years), and edge of colony (<2 years). Since graminoids compose the majority of forage used by livestock, I calculated the effects prairie dogs had on mean growing season biomass, crude protein, and digestible dry matter of graminoids in the valley. These attributes of the forage differed as a function of time colonized (table 1). For example, at the colony edge, mean graminoid biomass per unit area was only 28 percent lower than on adjacent off-colony sites, while on the oldest part of the colony it was 98 percent lower. Because of the higher leaf [N] in plants on colonies (Coppock and others, 1983a), however, the mass of crude protein per unit area was only 12 percent lower at the colony edge (compared to 28 percent lower biomass) than at off-colony sites. Similarly, prairie dog-induced reductions in mass of crude protein in other zones of the colony were not proportionately as great as reductions in graminoid biomass, although they were greater than at the colony edge (table 1). Similar trends occurred for mass of digestible dry matter per unit area, but the magnitude of the compensatory effect was not as great (i.e., reductions in digestible dry matter more closely matched reductions in graminoid biomass) as it was for crude protein (table 1).

The quantity-quality tradeoff also can be illustrated by estimating the total reductions in mean biomass, mass of crude protein, and mass of digestible dry matter attributable to prairie dogs in the entire valley, rather than on a unit area basis (table 1). These estimates were made by multiplying the mass per unit area by the area in each zone of the prairie dog town (table 1) and comparing the totals with the quantity that would have been present if prairie dogs were absent (assuming the same values on the colony as were present in uncolonized grassland). Although the prairie dog colony occupied 30 percent of the area of Pringle Valley, seasonal mean graminoid biomass was only 17.5 percent lower in the valley with prairie dogs present than it would have been with no prairie dogs present, while masses of crude protein and digestible dry matter were 14.6 percent and 16.6 percent lower, respectively. Therefore, had this valley been a paddock on a ranch, available graminoid biomass would have been reduced by prairie dogs proportionately slightly more than available mass of crude protein or digestible dry matter. The difference in the proportional reductions in crude protein and digestible dry matter relative to reductions in biomass represents the approximate magnitude of the quantity-quality tradeoff. Thus, the compensatory effect of prairie dog grazing on forage quality was small compared to their effect on graminoid biomass. It should be stressed, however, that these reductions are greatest on the oldest part of the colony, which suggests that small, relatively young colonies, such as those in areas periodically killed by plague, may have only a small effect on carrying capacity for large grazing animals.

Responses of Other Herbivores to Prairie Dog-Induced Vegetation Changes

Native Herbivores

Some older literature suggests that large native herbivores such as bison and pronghorn (*Antilocapra americana*) may forage preferentially within prairie dog colonies (King, 1955; Koford, 1958). Most of this early literature was based on anecdotal observations and was not well documented with data; however, several subsequent studies have confirmed that such a positive association between large native herbivores and prairie dogs may occur, at least under some conditions.

In northern mixed-grass prairie, Coppock and others (1983b) examined bison use of prairie dog colonies at two different scales in Wind Cave National Park: (1) parkwide use of colonies and (2) use of a single colony in the 120-ha Pringle Valley. The parkwide study involved driving a given route through the entire park three to four times per week from mid-May through mid-October and comparing the proportion of all bison observed that were on colonies to the proportion of landscape occupied by colonies (12 percent). Bison use of prairie dog colonies was greatest during midsummer and, when in the western portion of the park that contained most of the colonies, bison strongly preferred colonies. When their movement patterns took them to the east side of the park (which had fewer colonies), however, bison did not show a preference for prairie dog colonies. Thus, prairie dog colonies did not solely control bison herd movement in the park.

The Pringle Valley study involved mapping, from a nearby fire tower, the location of each bison that entered the valley (Coppock and others, 1983b). When in the valley, bison used the prairie dog colony preferentially over uncolonized portions of the valley. From June through mid-October, they used graminoid-dominated parts of the town two to three

Table 1. Effects of colonization by black-tailed prairie dogs (*Cynomys leucurus*) on seasonal mean mass of graminoids, crude protein in graminoids, and digestible graminoid dry matter in Pringle Valley, Wind Cave National Park, S. Dak. Values were calculated from data on graminoid biomass, nitrogen concentration, and digestibility measured by Coppock and others (1983a) from June 1 to October 1, 1979.

	Off colony	Edge of colony	Young colony	Old colony	Total	% change by prairie dogs
Area occupied (ha)	84	12	15	9	120	-30
Mass per unit area (kg/ha)						
Live graminoids	990	710 (-28%)	410 (-59%)	20 (-98%)	---	
Crude protein	80	71 (-12%)	41 (-49%)	2 (-90%)	---	
Digestible dry matter	499	383 (-23%)	221 (-56%)	11 (-98%)		
Mass in each zone (kg/zone)						
Live graminoids						
Prairie dogs present	83,160	8,520	6,150	180	98,010	-17.5
If prairie dogs were absent	83,160	11,880	14,850	8,910	118,800	
Crude protein						
Prairie dogs present	6,757	852	615	18	8,242	-14.6
If prairie dogs were absent	6,757	965	1,207	724	9,653	
Digestible dry matter						
Prairie dogs present	41,916	4,596	3,315	99	49,926	-16.6
If prairie dogs were absent	41,916	5,988	7,484	4,491	59,879	

times as much as would be predicted by random utilization, and grazing was a predominant activity there. Following a fire in adjacent, uncolonized grassland, bison continued to use the prairie dog colony preferentially but also used the burned area preferentially over the remaining uncolonized, unburned portion of the valley (Coppock and Detling, 1986).

A subsequent study by Krueger (1986) at Wind Cave National Park confirmed and extended this research in several ways. First, in a parkwide study similar to that of Coppock and others (1983b), Krueger (1986) confirmed that bison used prairie dog colonies preferentially. From April through November, about 42 percent of all her bison observations were on prairie dog towns, which covered 12 percent of the sample area. Second, similar to results of Coppock and others (1983b), bison strongly preferred graminoid-dominated parts of colonies (96 percent of all observations) to forb-dwarf shrub-dominated areas (Krueger, 1986). Third, pronghorn also used prairie dog colonies (67 percent of all observations) more frequently than expected from random use (12 percent), and 79 percent of all pronghorn Krueger observed on prairie dog colonies were in areas dominated by forbs and dwarf shrubs. Thus, while bison and pronghorn both used prairie dog colonies preferentially, they made use of different vegetation zones and plant resources within the colonies.

The patterns described above may be modified by precipitation or other weather that affects resources available to grazers. For example, Green (1998) found that bison at Wind Cave National Park used graminoid-dominated parts of prairie dog colonies in proportion to their availability during a year of below average precipitation and forage production; however, in the following year when precipitation and forage production were above normal, bison used these areas preferentially. During the intervening winter, bison avoided prairie dog colonies.

Livestock

Are cattle and other livestock attracted to prairie dog colonies as bison and pronghorn apparently often are? This topic has not been thoroughly researched, so the answer is not clear. On the shortgrass steppe in northern Colorado, cattle used prairie dog colonies approximately in proportion to their availability; that is, they neither preferred nor avoided them (Guenther and Detling, 2003). While on these colonies, however, cattle grazed as intensively as they did in grassland communities not colonized by prairie dogs. Because the shortgrass steppe is quite different from the mixed-grass prairie, it is not possible to say whether the lack of a preference for colonies by cattle was the result of differences in foraging behavior between cattle and bison or differences in large ungulate (e.g., bison and cattle) grazing behavior on shortgrass steppe versus mixed-grass prairie. The result may be more closely related to differences in grassland type, since a year of average precipitation on the shortgrass steppe is similar to a dry year such as that observed by Green (1998) on the mixed-grass prairie.

While this latter idea is somewhat speculative and not supported by data, it is supported by anecdotal observations.

One such observation came in a letter addressed to me and postmarked March 30, 1998, from Mr. Francis Bardanouve, a former long-time member of the House of Representatives in Montana. Mr. Bardanouve was writing in response to statements attributed to me by Long (1998), in which I suggested that bison and pronghorn may graze preferentially on prairie dog colonies because of the higher quality forage there compared to uncolonized areas. Mr. Bardanouve, a self-described lifelong rancher from an area of mixed-grass prairie in northern Montana, wrote:

> I never really [saw] many [prairie dogs] until I began leasing lands on the Ft. Belknap reservation. In a few places it had towns [i.e., colonies] of several hundred acres…[Prairie dogs] cut everything off down to a height of almost less than an inch…There is no grazing left where they are.
>
> However, I have had one mystery which I could never explain. I suddenly realized the answer in your statement. From time to time I would occasionally move cattle within the lease for some reason. What I could never explain was I would be moving them along fine without any trouble until I hit a prairie dog town. It never failed the movement of the bunch [of cattle] would come to a screeching halt. The bunch would begin grazing grass so short you could hardly see it and I could hardly get them moving. I would move one side of the bunch ahead a little and the rest would not move. I would then rush over and shove them ahead and the part that I had just pushed would quit moving. This slow zigzag movement would continue until we were off the "town site" and then the herd would take off at their normal pace.

Clearly, such anecdotal observations should not be taken as scientific evidence that cattle in mixed-grass prairie are attracted to prairie dog colonies as bison or pronghorn are; however, accounts such as these lend some credence to the idea and could perhaps be used as a justification for future studies to address this question.

Does Grazing by Other Herbivores Affect Expansion of Prairie Dog Colonies?

By the early 1900s, settlers and their livestock had moved into much of the Great Plains, and to some it was evident that prairie dog populations were increasing. C. Hart Merriam (1902, p. 263), the former chief of the U.S. Bureau of Biological Survey, noted that "prairie dogs are now more abundant than formerly and their colonies have overspread extensive areas previously unoccupied." He attributed this increase to human-related factors, particularly (1) increasing the food supply for prairie dogs via cultivation of the soil and (2) decreasing the abundance of their natural enemies such as coyotes (*Canis latrans*), badgers (*Taxidea taxus*), hawks, owls, and snakes. Merriam (1902) recognized that prairie dogs caused substantial losses of forage and crops, but he apparently failed to consider that grazing and trampling of vegetation by settlers' livestock might have contributed to the rapid expansion of prairie dog populations.

By the mid-20th century, a number of researchers were beginning to recognize that large grazers might be responsible for expansion of prairie dog colonies. At the Wichita Mountains Wildlife Refuge in southwestern Oklahoma, Osborn and Allan (1949) studied a prairie dog colony that had been designated for complete protection from poisoning. Following termination of all cattle grazing permits in 1937, only native ungulates and a small group of longhorns grazed the 24,000-ha refuge, and very few grazed in the vicinity of this colony. Over the next decade, the study colony completely disappeared. Prairie dogs were known to be a shortgrass plains species and had previously been observed to spread into surrounding vegetation following overgrazing. Therefore, Osborn and Allan (1949) concluded that their initial presence on this site, whose natural climax vegetation was dominated by tall grasses, resulted from heavy grazing during its earlier use as cattle range. Following removal of cattle, they reasoned, grass cover increased in stature and density, and the prairie dogs were restricted to smaller and smaller areas until they eventually died out. By contrast, other colonies at the refuge persisted in spite of at least limited poisoning, but these colonies received regular grazing by bison and other big game (Osborn and Allan, 1949).

The idea that prairie dogs could expand more readily into short vegetation was supported by King's (1955) observations in the mixed-grass prairie of Wind Cave National Park. There, he observed that prairie dogs "invaded" a limestone outcrop covered with short vegetation about 100 m away from the parent colony rather than areas of taller vegetation adjacent to the existing colony. King (1955, p. 105) suggested "that short vegetation may encourage prairie dogs to settle a new area" and that they "seem to select vegetation that is neither too rank nor too tall" as they colonize new areas.

Following his study of prairie dog colonies in northern mixed-grass prairie, shortgrass steppe, and southern mixed-grass prairie, Koford (1958) also noted that prairie dog expansion was favored by shorter, less dense vegetation. In particular, Koford remarked (p. 63) that stands of tall grass surrounding prairie dog colonies could act as effective barriers to expansion, and that prairie dogs "seldom enter grass so tall and thick that they cannot see through or over it." Moreover, he noted (p. 65) that prairie dogs rarely expanded into rangeland that was in good to excellent condition and (p. 67) that "heavy grazing [by livestock] tends to reduce the barriers and allow the spread of prairie dogs." While Koford (1958, p. 67) felt that "conservative grazing" would allow vegetation to grow taller and inhibit prairie dog expansion, he also pointed out that this might not occur in more arid grasslands such as the shortgrass steppe. In support of this idea, Snell and Hlavachick (1980) observed that, after 4 years of rest from livestock grazing during the growing season in southern Kansas, native grasses on a prairie dog colony had become more abundant and the colony had decreased in area from about 45 ha to 5 ha.

Results from more recent studies are consistent with these earlier anecdotal observations and interpretations. For example, in northern mixed-grass prairie in South Dakota, Uresk and Bjugstad (1983) found an average of 106 active prairie dog burrows per hectare on sites where no cattle grazed and more than twice as many (235/ha) where cattle and prairie dogs grazed. They attributed the lower burrow density where cattle were excluded to taller vegetation there and concluded that high prairie dog densities were more likely to occur when rangelands are heavily grazed. In northeastern Montana, Knowles (1986) found that over 60 percent of the colonies he surveyed were on pastures with heavily grazed livestock developments and that nearly all (>97 percent) occurred adjacent to trails and roads. Interviews with landowners and managers suggested to Knowles (1986) that colonization of these areas by prairie dogs followed, rather than preceded, intensive grazing and soil disturbance. Likewise, Licht and Sanchez (1993) suggested that creation of cattle point attractants (e.g., water tanks and supplementary feeding sites) encourages colonization by prairie dogs after vegetation height around the attractants is reduced by livestock grazing and trampling. Similarly, Truett and Savage (1998) noted that expansion of introduced prairie dogs into Chihuahuan Desert grasslands typically only occurred where vegetation was less than 20–25 cm tall. Following mowing of taller vegetation, prairie dogs quickly moved into the mowed areas.

Scholarly reviews of the literature and early accounts of prairie dog interactions with large native and introduced herbivores such as bison and cattle led Truett and others (2001) and Truett (2003) to many of the same conclusions. Specifically, prior to extensive settlement of the Great Plains, the distribution of prairie dogs in more productive grasslands was closely linked to areas frequented by bison, which kept the grass relatively short. Following removal of bison, the range of prairie dogs shrank until cattle were introduced in large numbers, thereby allowing prairie dog populations to expand again. In areas where cattle were introduced soon after extermination of bison, prairie dogs persisted in large numbers; however, severe long-term overgrazing by livestock may reduce densities of prairie dogs by reducing availability of forage resources (Desmond, 2004).

Conclusions

The literature reviewed here suggests a strong interactive relationship between prairie dogs and other grazers, particularly in relatively productive grasslands. We have seen that, as a result of selectively grazing graminoids and clipping the vegetation to a short height, prairie dogs may greatly reduce aboveground plant biomass and cover, change plant species composition towards a greater dominance by forbs, and enhance the quality of the remaining forage via increases in leaf [N] and digestibility. Native grazers, such as bison and pronghorn, as well as cattle, may be attracted to these colonies as preferred sites to graze. Where densities of large grazers are relatively high, their grazing and trampling activities in uncolonized grassland may make some sites more suitable for colonization by prairie dogs and thereby facilitate expansion of prairie dog populations. While much of this latter concept is based on anecdotal reports rather than on experimental results, the preponderance of similar reports (Truett and others, 2001; Truett, 2003) lends credibility to it. In grasslands such as the semiarid shortgrass steppe, where vegetation is naturally shorter and dominated by species such as blue grama, the strength of many of the interactions between prairie dogs and large grazers discussed above is apparently not as strong.

Shooting Prairie Dogs

By Archie F. Reeve[1,2] and Timothy C. Vosburgh[3]

Abstract

Recreational shooting of prairie dogs (*Cynomys* spp.) has occurred for many years, but interest and intensity have increased dramatically in the past decade. Shooting can cause prairie dogs to change their behavior and can affect sex and age groups differently. Prairie dog populations are capable of recovering from shooting or other reductions, but time to full recovery depends on demographic parameters (survivorship and fecundity). Simple population growth models with demographic variability demonstrate less risk of population extinction when shooting is regulated by effort rather than by quotas on numbers shot. Landowners might consider allowing shooting as a source of income, but, if not closely managed, shooters potentially can eliminate small colonies. Predation by black-footed ferrets (*Mustela nigripes*) probably does not significantly depress prairie dog populations. Prairie dog mortality caused by unregulated recreational shooting can vastly exceed predation by black-footed ferrets, affecting prairie dog survivorship and potentially affecting fecundity and recruitment. Until effects of shooting prairie dogs as prey for black-footed ferrets are better understood, shooting closures on reintroduction sites are appropriate.

Keywords: black-footed ferret, *Cynomys* spp., *Mustela nigripes*, prairie dog, recreational shooting

Introduction

Many long-time residents of western States recall spending summer vacations “plinking” prairie dogs (*Cynomys* spp.), whether by wrist rocket, air gun, or .22 caliber rifle. For over 100 years, shooting black-tailed prairie dogs (*C. ludovicianus*) in rural Kansas, for example, was common on Sunday afternoons by self-styled “varmint hunters” and by after-school target shooters (Smith, 1967). Shooting prairie dogs has been and continues to be primarily for sport but now involves marksmen who utilize high-technology rifles while practicing their shooting skills. To hone their skills, many shooters use a variety of rifles, scopes, range finders, shooting benches, and reloading equipment. Indeed, shooting prairie dogs at distances >450 m entitles one to membership in the 500 Yard Club, sponsored by the Varmint Hunters Association, and some members have registered successful shots >1,350 m.

Many shooters come from out of State (Vosburgh, 2000; South Dakota Prairie Dog Work Group, 2001), but this appears to be a recent phenomenon. In North Dakota, for example, nonresidents must purchase either a nongame license or a combination nongame and furbearer license to shoot prairie dogs; residents are exempt (North Dakota Game and Fish Department, 2001). The number of nonresident nongame licenses sold increased from 36 in 1975 to 625 in 2001, while nonresident nongame and furbearer license sales increased from 163 in 1989 to 1,326 in 2001 (S. Hagen, written commun., 2003). The recent increase in license sales to nonresidents in North Dakota indicates the rise in recreational shooting of prairie dogs by people from out of State. Similarly, in South Dakota over 35 percent of the estimated 16,011 prairie dog shooters on nontribal land in 2001 were nonresidents (Gigliotti, 2001).

Shooting Intensity

Available information indicates that substantial numbers of prairie dogs have been shot. In 2000, recreational shooters killed 1,186,272 prairie dogs on nontribal lands in South Dakota (South Dakota Prairie Dog Work Group, 2001). The number killed on nontribal lands increased to 1,516,174 in 2001 (Gigliotti, 2001). Shooters spent a total of 75,059 recreation days to kill that many prairie dogs: 54,849 by residents and 20,210 by nonresidents (Gigliotti, 2001).

During 1998 in Nebraska, 7,100 shooters spent 33,400 recreation days killing 301,000 prairie dogs; in 1999, fewer shooters (5,970) spent less time (28,300 recreation days) to kill more prairie dogs (356,000) (Nebraska Game and Parks Commission, 2001). The Colorado Division of Wildlife (2002) estimated (with ±95 percent confidence interval) that 6,070 shooters (±629) killed 418,412 prairie dogs (±75,234) during 64,674 recreation days (±825) in the 1998–99 reporting period. Based on these data, shooter success rates (number killed per recreation day) appear similar among reporting States: 6.5 killed per day in Colorado (between 5.2 and 7.7), 12.6 killed per day in Nebraska in 1999, and 20.3 killed per day in South Dakota in 2001.

Estimates of prairie dogs killed in individual States depend on shooters' responses to survey questionnaires, which are possible only when shooters are licensed, such as in South Dakota and Colorado (South Dakota Prairie Dog Work Group, 2001; Colorado Division of Wildlife, 2002, 2003). On the other hand, nontribal recreational shooters on some tribal lands are required to be accompanied by a guide and must fill out a questionnaire that includes the number of days spent shooting, number of rounds fired, and estimated number of prairie dogs killed. In 2000, 936 shooters fired 156,307 rounds to kill 57,848 prairie dogs on the Rosebud Indian Reservation (T. Vosburgh, unpub. data, 2002). That rate of one prairie dog killed per 2.7 rounds fired is similar to an observed rate of one prairie dog killed per 3.0 shots fired on the Fort Belknap Indian Reservation in northern Montana during 2001 (Vosburgh, 2000).

The Lower Brule Indian Reservation in central South Dakota has collected 9 years of black-tailed prairie dog harvest data (table 1). From 1993 to 2001, an average of 121 licensed recreational shooters killed an average of 14,200 prairie dogs per year while spending an average of 372 recreation days on the reservation (Lower Brule Sioux Tribe, 2002). Each shooter averaged 118 prairie dogs shot per year or about 38 shot per day. That level of success is comparable to nonresident shooters on nontribal lands in South Dakota who, in 2001, spent an average of 3.5 days per shooter to kill 36 prairie dogs per day (Gigliotti, 2001). The average success rate was higher than reported above by Nebraska or Colorado. Relatively high levels of shooter success may be due to tribes' interest in recreational shooting as a source of revenue with concomitant monitoring of shooting effects on prairie dog populations. Also, out-of-State shooters may be especially diligent in pursuit of their quarry. During 2001, residents of South Dakota shot an average of 14 prairie dogs per day, considerably fewer than the 36 prairie dogs per day reported shot by nonresidents (Gigliotti, 2001).

Shooter success rates appear related to prairie dog densities. Typical densities of black-tailed prairie dogs exceed those of white-tailed prairie dogs (*C. leucurus*) (Tileston and Lechleitner, 1966), whereas densities of Gunnison's prairie dogs (*C. gunnisoni*) are intermediate or overlap those of the other two species (Fitzgerald and others, 1994). All three species are shot in Colorado, but harvest estimates are not reported by species, only by county (Colorado Division of Wildlife, 2003). Based on species' distributions (Fitzgerald and others, 1994), we estimated harvest for the three species (table 2). Although ranges of shooting success rates overlap, shooters in 2002–03 killed more prairie dogs per recreation day in counties with black-tailed prairie dogs than in counties inhabited by Gunnison's and/or white-tailed prairie dogs (table 2).

Effects of Shooting on Individual Prairie Dogs

Prairie dogs subjected to shooting change their behavior. In Montana, black-tailed prairie dogs in colonies with recreational shooting spent less time above ground than did prairie dogs in colonies with no shooting. When above ground, the former devoted less time to feeding and more time to scanning than the latter (Vosburgh and Irby, 1998). Prairie dogs in colonies with recreational shooting are more likely to escape when approached on foot or by vehicle, retreating to burrows sooner than prairie dogs not subjected to shooting (Vosburgh and Irby, 1998; Keffer and others, 2000). Increased alertness and early escape by prairie dogs are potential problems for recreational shooters, though some shooters may by more interested in shooting skill and firearm accuracy than in numbers of prairie dogs killed.

The timing of shooting prairie dogs may affect reproduction and mortality of various sex and age groups. Shooting from March to May is likely to kill pregnant or lactating females so that neither they nor their offspring will reproduce the following year (Knowles, 1988). Shooters generally cannot distinguish between male and female prairie dogs and, except during early summer, between adults and juveniles. Juvenile prairie dogs are more susceptible than adults to low levels

[a] Counties within species' distributions as described by Fitzgerald and others (1994).

[b] Colorado Division of Wildlife (2003).

of shooting (Keffer and others, 2000). For example, when a colony having 35 percent juveniles was subjected to a 10 percent harvest during early to mid-summer, 53 percent of the animals killed were juveniles. On the same colony, adult females and adult males (39 percent and 26 percent of the population, respectively) were killed proportionately less than their occurrence in the population. Higher shooting pressure (>20 percent mortality) on another colony also targeted juveniles disproportionately (Keffer and others, 2000).

Adult females, including yearlings, appear more vulnerable to shooting than do adult and yearling males (Vosburgh and Irby, 1998; Keffer and others, 2000). During early summer 1995 in Montana, for example, the ratio of adult males to females was 92:100 on nine colonies (Vosburgh and Irby, 1998). In late summer, after an average of 8.5 hours of shooting per colony, the ratio of adult males to adult females was 167:100 on the same nine colonies. Survivorship of adult females during shooting was only 57 percent of the survivorship of adult males. On eight control colonies with no shooting, adult female survivorship was 122 percent of adult male survivorship between early and late summer in the same year (Vosburgh and Irby, 1998), which is similar to differential survival of unhunted black-tailed prairie dog populations elsewhere (Hoogland, 1995). Greater vulnerability of females probably exacerbates the impact of shooting by diminishing future reproduction.

Reproduction by adult and yearling female prairie dogs may be suppressed on colonies that are subject to continual recreational shooting. In North Dakota, only 32 percent of yearling female black-tailed prairie dogs on colonies disturbed by >20 years of heavy shooting reproduced (based on placental scars and evidence of ovulation) compared with 90 percent of yearling females on colonies relatively undisturbed by shooting (Stockrahm and Seabloom, 1988). Counts of placental scars in adult females ($\geq$2 years old) examined from the disturbed colonies were significantly lower than in adult females on relatively undisturbed colonies, indicating depressed reproduction on the disturbed colonies. These observations do not demonstrate that continual shooting was solely responsible for depressed reproduction because the disturbed colonies were spatially confined and not growing, whereas the undisturbed colonies were not spatially restricted and had doubled in size during the previous 5 years (Stockrahm and Seabloom, 1988). Depressed reproduction in the disturbed though confined colonies, especially by yearling females, may indicate density-dependent processes similar to those observed by Garrett and others (1982) in South Dakota.

Effects of Shooting on Prairie Dog Populations

Populations increase with birth and immigration of individuals but decrease with their death or emigration. For species such as prairie dogs that reproduce once a year (Hoogland, 1995) but die from various sources throughout the year, information about the rate of population increase (sometimes called the "finite rate of increase" and symbolized here by R; others often use lambda, λ) is important to understanding potential effects of recreational shooting on colonies. The equation $N_t = N_0 R^t$ can be used to compute population size at time t, N_t, if the initial population size, N_0, and R are known.

Finite rates of increase in prairie dog colonies with no shooting vary from year to year. For example, at one black-tailed prairie dog colony in Wind Cave National Park, S. Dak., colony size increased in some years but declined in others. Population finite rates of increase at this colony averaged 1.03 (1 standard deviation = 0.25), with minimum R = 0.70 and maximum R = 1.45 (Hoogland, 1995, table 16.1). Because this colony was surrounded by unsuitable habitat, its area remained constant, so the observed R = 1.0 might have been expected. Stationary populations often increase in response to factors such as addition of food, increase in habitable area, and population reduction (Caughley and Sinclair, 1994). Population reduction decreases competition, usually for food. With more food per individual, reproduction increases, mortality decreases, and the population grows (Caughley and Sinclair, 1994).

Limited experimental evidence demonstrates that removing prairie dogs, by shooting or other means, enhances population growth rates. After 2 consecutive years of shooting at two small black-tailed prairie dog colonies, populations were reduced or eliminated; in the year after shooting ceased, portions of both colonies were still inactive (Knowles, 1988). Five years after the shooting program ended, the larger of the two shot colonies had expanded to cover 140 percent of its preshooting area, and the smaller had grown to cover 90 percent of its former area (Knowles, 1988). Spatial growth of these treatment colonies resulted from increased numbers of prairie dogs, but details of population increase—whether by immigration from neighboring colonies or as a demographic response of the surviving prairie dogs—are unavailable. Data on active versus inactive burrow entrances indicate a similar response to cessation of shooting at larger black-tailed prairie dog colonies in South Dakota. Less than 45 percent of total burrows were active while recreational shooting was allowed, but, after 4 years without shooting, 74 percent of burrow entrances were active (B. Perry, unpub. data, 2000).

Rates of population increase have been documented under other conditions that reduce prairie dog populations. Knowles (1986) studied the effects of a toxicant, zinc phosphide, on several black-tailed prairie dog colonies by different treatment regimes and then observed the population recoveries for up to 5 years following the treatments. Knowles computed instantaneous growth rates for each year during population recovery. The instantaneous growth rate, r, is related to the finite rate of increase, R, by $R = e^r$, (Akçakaya and others, 1999) and is employed to predict population growth in continuous time rather than in discrete time, by the equation $N_t = N_0 e^{rt}$. One month after treatments that attempted to completely eradicate two colonies, Knowles (1986) estimated a reduction of 95 percent caused by the treatments. By continuing to monitor population recovery, Knowles computed average r = 0.916 (R = 2.499) after 1 year, r = 1.069 (R = 2.912) from the first to the second year and r = 0.350 (R = 1.419) from the second to the fifth year. For the five colonies that received partial toxicant treatment, which reduced target populations to an average of 19 percent of pretreatment levels, average r = 1.339 (R = 3.815) after 1 year and r = 0.148 (R = 1.160) from the first to the second year (Knowles, 1986).

Values for R reported by Knowles (1986) were higher for both study groups after the first year following treatments than values observed on a prairie dog colony in Wind Cave National Park, S. Dak. That colony expanded from 0.47 ha to 1.86 ha over a 3-year period (Garrett and Franklin, 1988) when colony size in June increased from 51 to 134 adults and juveniles (average R = 1.38). Similarly, a black-tailed prairie dog colony near Nunn, Colo., with no population reduction treatment, expanded from 2.1 ha to 3 ha in 1 year as the colony size in June grew from 28 to 82 animals (Koford, 1958, p. 10, table 1). For that colony in that 1-year period, R = 2.93, but in the previous year the colony had declined from 50 to 28 animals (R = 0.56).

Population responses were also tracked following reduction of two colonies in South Dakota by translocating live-trapped black-tailed prairie dogs (Radcliffe, 1992). After intensive removal during June of the first study year, 6 prairie dogs remained in one of the colonies, but 10 were present by June of the following year. By June of the second year following removal, the population had increased to 51 prairie dogs, but the increase was mostly attributed to immigration (Radcliffe, 1992). The second colony also grew substantially after the population was reduced to 10 individuals in June of the treatment year. By the next June that colony had grown to 23 and by June of the second year had grown to 80 prairie dogs; the extraordinary growth rate during the second year was R = 3.48. In this second colony, immigration played a minor role (three immigrated annually). Population growth mainly resulted from increased litter size and higher juvenile survivorship (Radcliffe, 1992).

These data support our earlier generalization that populations can be stimulated to grow by reducing the number of animals that compete for a limited resource. Similar population responses were noted in colonies of Gunnison's prairie dog during and after a sylvatic plague epizootic in Moreno Valley, N. Mex. Cully (1997) found that after plague killed more than 99 percent of the population, the few surviving prairie dogs formed two colonies in areas that were previously unoccupied. Using Leslie matrix analysis involving demographic parameters (survivorship and fecundity), Cully found that the population would be nearly tripling each year. The key to this high rate of population growth was found to be yearling females reproducing at a rate similar to that of adults and having a relatively high survival rate (Cully, 1997). Similarly, the survival rate of juveniles (90 percent) in a young, expanding black-tailed prairie dog colony in South Dakota was significantly higher than juvenile survivorship (49 percent) in an older, nonexpanding colony (Garrett and others, 1982). In addition, yearling females on the younger colony were more likely to produce and wean a litter than were those on the older colony. These two demographic characteristics of juveniles and yearlings appear consistent in rapidly growing prairie dog populations.

Simulated Effects of Different Shooting Strategies

In many of these studies, prairie dog populations appear to exhibit density-dependent growth; crowding with concomitant diminishing resources available to each individual leads to increased mortality (decreased survival), decreased reproduction, and/or increased emigration. An assumption of density-dependent population growth is that when a population approaches carrying capacity (K) the growth rate declines and eventually reaches R = 1.0 when N = K. The value of R at time t, R_t, depends on the population size N_t relative to K according to the equation, $R_t = R_{max}^{(1 - N_t/K)}$. When the population N_t is small, the exponent $(1 – N_t/K)$ is close to 1 and the population's growth rate R_t is close to the maximum possible, or R_{max}. As the population grows and approaches its carrying capacity, the growth rate R is much less than R_{max}, and when the population reaches carrying capacity, R = 1.0 because the exponent $(1 - N_t/K) = 0$.

If prairie dogs are viewed as an economic resource, the best strategy is to manage colonies for a sustained yield. A landowner or wildlife manager hoping to capitalize on prairie dog harvest might allow shooters to kill as many prairie dogs in a year as are produced. With density-dependent growth (R_{max} = 2.00, K = 1,000), a population growing from 20 to 1,000 animals produces the maximum number of animals (maximum yield) when it is approximately at half of carrying capacity (Peek, 1986). In this example, maximum yield = 209 when the population reaches 438 after 5 years of growth.

Harvesting the population at maximum productivity maximizes yield, but managing for maximum yield is difficult (Caughley and Sinclair, 1994). Removing animals from a population reduces the base population. The difficult task is determining what base population produces the best yield for the next year. If the harvest exceeds maximum yield and continues over time, the population will eventually decline to zero (Caughley and Sinclair, 1994).

Two common approaches to control harvest are (a) imposing a quota on numbers harvested and (b) regulating harvesting effort (Caughley and Sinclair, 1994). Regulating harvest by quotas is conceptually attractive: once the quota is attained, shooting stops. Determining when quotas for prairie dogs are reached might be problematic, however. If shooters consistently record prairie dogs killed and number of rounds fired, wildlife managers can estimate the number killed from the number of shots. Figure 1 demonstrates the problem with fixed annual harvest quotas. An initial population of 1,000 eventually stabilizes at 585 animals in 24 years if 195 prairie dogs are shot each year, but if the annual harvest exceeds 209 animals (the maximum yield when R_{max} = 2.00 and K = 1,000), then the population declines to extinction, doing so faster with larger harvests.

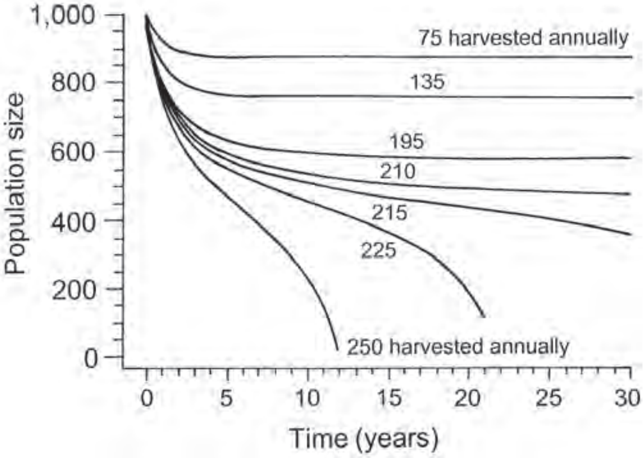

Figure 1. Effects of constant annual harvest quotas on a population with density-dependent growth (R_{max} = 2.00, K = 1,000) but no random variation in R_t. Annual harvest >209 animals (maximum yield) cannot be sustained, and the population eventually declines to zero.

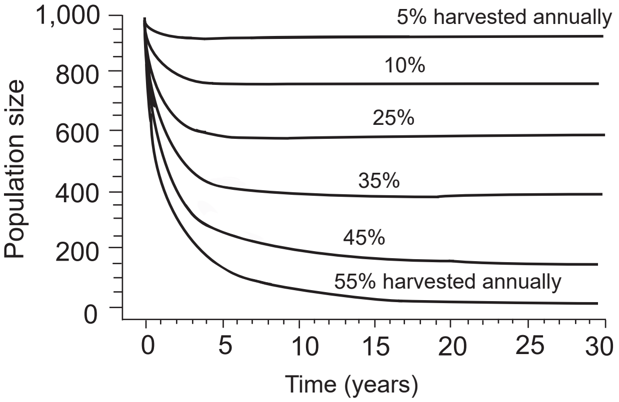

Figure 2. Deterministic predictions of a population with density-dependent growth (R_{max} = 2.00, K = 1,000) subject to different levels of proportional harvest annually.

Theoretically, controlling harvest effort removes some proportion of the population over time rather than a fixed number of animals each year. One way to control harvest effort is to limit the timing and duration of the harvest. Another way is to limit the number of shooters (Caughley and Sinclair, 1994). Figure 2 shows the outcome of various annual harvest levels as percentages of the current population. At an annual harvest rate of 25 percent, the population stabilizes at 585 animals, but in only 13 years, while the long-term average harvest (from t = 0 to t = 30) is approximately 199 animals.

To this point, population growth was assumed to be deterministic with no uncertainty in birth or death rates. Environmental variation from year to year, or day to day, and from one locale to another causes fluctuations in prairie dog populations' birth and death rates (Hoogland, 1995). In addition, individual animals in the same population have different reproductive capabilities or chances of survival. Recreational shooting of prairie dogs introduces additional uncertainty in population demographic parameters since age groups and sexes may be affected differently. Levels of variability might be measured at some point in time but cannot be predicted in the future. Stochastic population models provide for such uncertainty.

In the simulation examples provided so far, the finite rate of increase at time t, R_t, is equal to $R_{max}^{(1-Nt/K)}$. Annual variation in rates of birth, immigration, death, and emigration all contribute to variability of R_t. Annual variation in carrying capacity also causes variation in R_t. We introduce variation by increasing or decreasing the computed value of R_t by a random amount but within some defined limits, for example within ±20 percent of the computed value for R_t, which includes demographic variation as well as random variation in carrying capacity.

This simple approach was applied in 100 simulations to project population growth from an initial population of 20 animals with $R_{max} = 2.0$ and $K = 1{,}000$. The simulations show that the average population size stabilizes at approximately 1,000 animals (fig. 3) but, because of random variability of R_t, the population at $t = 15$ could range from 797 to 1,230 animals in any one simulation.

Random variation, now limited to only ±15 percent of the computed value for R_t, for example, is used to predict how an initial population of 1,000 ($N_0 = K$) with $R_{max} = 2.0$ responds to an annual quota of 195 animals harvested. The results (fig. 4) are different from those generated by the deterministic model (fig. 1). After 1,000 simulations, the stochastic model predicts a population of 406 (ranging from 0 to 819) at the end of 30 years with average annual harvest of 183. The model also predicts a 23 percent chance that the population will become extinct by $t = 30$. Risk of extinction increases with level of random variation in R_t. For example, with random variation ±10 percent of R_t, extinction within 30 years occurred in 1 percent of the trials, but a 46 percent chance of extinction is expected with random variation ±20 percent of R_t (after 1,000 simulations with an annual quota of 195).

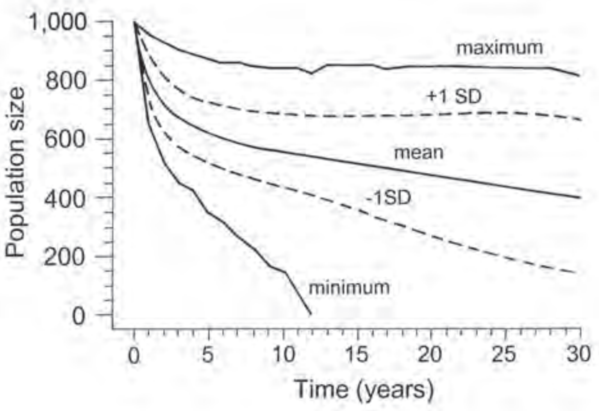

Figure 4. Results of 1,000 simulations with an annual harvest quota of 195 animals, an initial population of 1,000 animals, density-dependent population growth ($R_{max} = 2.00$), and random variation in the population growth rate each year (within ±15% of R_t after computation as $R_t = R_{max}^{(1-Nt/K)}$).

Alternatively, an annual harvest rate of 25 percent produces an expected population of 580 animals (ranging from 439 to 744 animals) after 30 years of simulation with average annual harvest of 197 animals but poses no risk of extinction (fig. 5), unlike the risk observed with fixed quota harvest (fig. 4). With demographic and environmental uncertainty, sustainable populations are more likely if harvested proportionally rather than by fixed quota. Implicit in modeling these two harvest strategies, however, is intensity of harvest management. Once set, the quota of 195 harvested did not change over time even though the population may have been declining

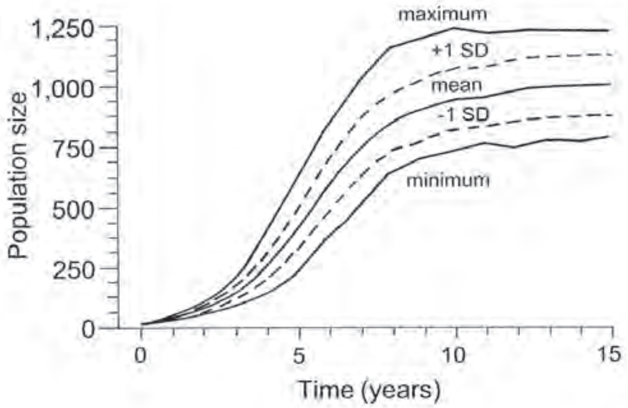

Figure 3. Results of 100 simulations of density-dependent population growth ($R_{max} = 2.00$, $K = 1{,}000$), but with random variation in the population growth rate each year (within ± 20% of R_t after computation as $R_t = R_{max}^{(1-Nt/K)}$).

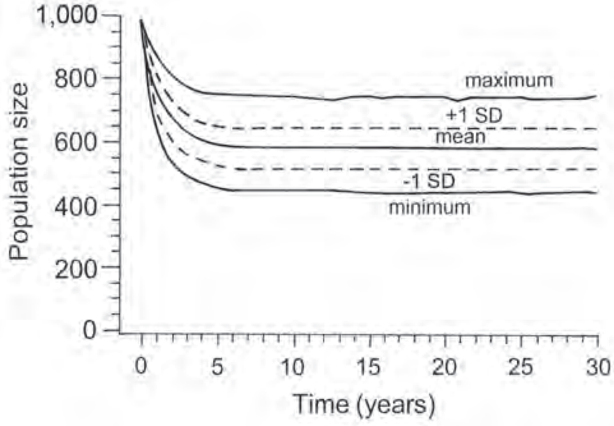

Figure 5. Results of 1,000 simulations with an annual harvest rate of 25%, an initial population of 1,000 animals, density-dependent population growth with $R_{max} = 2.00$, and random variation in the population growth rate each year (within ±15% of R_t after computation as $R_t = R_{max}^{(1-Nt/K)}$).

in a given simulation. Alternatively, numbers harvested were continuously adjusted when a harvest rate of 25 percent was applied. To ensure a sustainable population while realizing a desired annual harvest, the manager must monitor the dynamics of the target population and respond accordingly.

Proper application of either harvest strategy, whether by regulating harvest quota or by regulating harvesting effort, requires knowledge of the target population's carrying capacity and the species' R_{max}. Seldom are these parameters known with any certainty. A population at approximately K/2 is expected to yield the maximum number of animals that, in theory, could be harvested each year as a maximum sustained yield (MSY). Nevertheless, stochastic events in the environment and variability among individuals in a population can lead to substantial population fluctuations, and harvest should always be well below the estimated MSY (Caughley and Sinclair, 1994).

A third approach involves harvesting only when a population exceeds some threshold level, above which excess animals are taken (Lande and others, 1997). Threshold harvesting requires specific knowledge about population levels but produces high annual variation in harvest because populations below the threshold are not harvested (Lande and others, 1997). Threshold harvesting might be possible if a manager or landowner had never attempted to control prairie dogs and had monitored population levels under various environmental conditions so that average K could be estimated.

Recreational Shooting on Private Land for Prairie Dog Conservation

Of >660 livestock and agricultural operators surveyed in eastern Wyoming (Wyoming Agricultural Statistics Service, 2001), 23 percent expressed interest in a program of financial compensation for allowing prairie dogs on their land. The survey posed four types of management programs to respondents who expressed interest in financial compensation: (a) a shooting management program, (b) a cooperative shooter placement program to direct shooters to landowners willing to allow shooting, (c) a program to develop markets for prairie dogs as pets or for nature photography, and (d) a banking program in which other States would compensate Wyoming landowners for conserving prairie dogs (Wyoming Agricultural Statistics Service, 2001). Of these, prairie dog banking was the most popular (59 percent interested), a cooperative shooter placement program (57 percent interested) was second, followed by interest in shooting management (51 percent of respondents).

Respondents who expressed interest in programs with financial compensation considered \$74−\$86/ha annually to be reasonable (\$30−\$35/acre, median value). Generally, interest in maintaining or increasing the number of acres of prairie dog colonies on their land varied directly with the level of financial compensation. To attain \$74−\$86/ha in potential income from shooting, a landowner with 405 ha (1,000 acres) of prairie dog colonies, for example, could charge four shooters \$79−\$92 per person per day to shoot during the period between Memorial Day and Labor Day (approximately 95 days). Four shooters during that period are equivalent to 380 recreation days. Applying data from the Fort Belknap Indian Reservation (average of 38 prairie dogs shot per recreation day), the annual toll would be 14,440 prairie dogs killed, whereas 2,470 killed would be expected in a year at the rate of 6.5 prairie dogs per recreation day estimated in Colorado.

Densities of black-tailed prairie dogs in Conata Basin, S. Dak., range from 8/ha to 41/ha (Severson and Plumb, 1998). If that range of densities is applied to the simple example of a 405-ha colony on private land, then the population, estimated between 3,240 and 16,605 prairie dogs, could eventually be eliminated by recreational shooting under either the shooter success rate on Fort Belknap Indian Reservation or in Colorado. To ensure a future income, the private landowner would have to significantly decrease the number of recreation days spent shooting, which should concomitantly decrease the number of prairie dogs shot. In addition, to attain the desired income, the landowner would have to substantially increase fees charged per shooter.

Managing prairie dogs on private land for recreational shooting might be appropriate for some landowners and not others. Still, when faced with the apparent need or desire to control prairie dogs, opening land to shooters can provide landowners with an additional source of income and thus an incentive to support some level of occupied habitat that they otherwise would not tolerate.

Recreational Shooting on Black-footed Ferret Reintroduction Sites

Recreational shooting of prairie dogs has been totally or partially restricted on black-footed ferret (*Mustela nigripes*) reintroduction sites (Colorado Division of Wildlife and others, 2002), although there are few instances where effects of shooting closures on prairie dog populations have been monitored. In some instances, shooting closures coincided with changes in statewide prairie dog management practices following States' adoption of the Black-tailed Prairie Dog Conservation Assessment and Strategy and addendum (Luce, 2001). Closures to shooting have also been applied to other species of prairie dog, as in Arizona where black-footed ferrets were introduced in Gunnison's prairie dog colonies (B. Van Pelt, oral commun., 2003). In other cases, shooting closures were initiated to improve habitat for introduced black-footed ferrets and to ensure that ferrets, especially kits, would not be inadvertently shot (B. Perry, oral commun., 2003). Other wildlife, burrowing owls (*Athene cunicularia*) in particular, can be killed during recreational shooting of prairie dogs. Though not documented as a consequence of shooting prairie dogs, there are instances of substantial burrowing owl mortality by shooting (Haug and others, 1993; James and Espie, 1997).

In its review of a petition to list the black-tailed prairie dog under the Endangered Species Act, the U.S. Fish and Wildlife Service (1999) evaluated effects of recreational shooting, concluding in part that shooting may be a compensatory source of mortality in large populations with substantial reproduction. Where small prairie dog populations are depressed by other factors such as disease, shooting may be an additive source of mortality. Compensatory mortality, where one source of mortality offsets or replaces another source (Mackie and others, 1990), whether caused by harvest or predation, is most likely to occur in populations near their ecological equilibrium or carrying capacity (Peek, 1986; Bartmann and others, 1992; Boyce, 2000). In such density-dependent regulated populations, when density is high so are mortality rates, and a population decrease by whatever means results in higher survivorship in the remaining population, as long as removal of animals does not adversely affect reproduction the following year. When removal by harvest and/or predation is high enough to affect reproduction in subsequent years, mortality from those sources is likely to be additive and, if extreme, can force the target population to extinction.

By most accounts, ferret predation does not significantly depress prairie dog populations (Fagerstone, 1987) and would seem a source of compensatory mortality. Biggins and others (1993) estimated annual consumption of 109 prairie dogs by one black-footed ferret family group (1 adult female, 3.3 young, and 0.5 adult male) while recognizing the potential for substantial prairie dog predation by other species. Assuming moderate levels of mortality by other sources, Biggins and others (1993) estimated that a stable population of 763 prairie dogs would sustain a ferret family group for 1 year. Using an age-dependent predation model of ferrets and prairie dogs, Klebanoff and others (1991) concluded that as many as 2,000 prairie dogs per ferret may be necessary to sustain a stable predator-prey system. A stable system can also be attained with fewer prairie dogs—though not as few as 763—but only if prairie dog survivorship or fecundity rates increase (Klebanoff and others, 1991). We are not aware if either estimation approach has been field tested.

Prairie dog mortality by unregulated recreational shooters can vastly exceed predation by black-footed ferrets, thus affecting prairie dog survivorship and potentially affecting fecundity and recruitment. Recreational shooting can be additive mortality, potentially more so on black-tailed prairie dog colonies than on Gunnison's or white-tailed colonies (table 2). Management agencies have recognized that, even with closures of specific areas, recreational shooting has continued and that enforcement of shooting closures is problematic (V. Kopcso, oral commun., 2003). Until more is known about effects of recreational shooting on prairie dogs that are the primary prey resource for black-footed ferrets, managers are wise to restrict shooting and enforce closures, particularly on ferret reintroduction sites inhabited by black-tailed prairie dogs.

Habitat Preferences and Intraspecific Competition in Black-footed Ferrets

By Dean E. Biggins,[1] Jerry L. Godbey,[1] Marc R. Matchett,[2] and Travis M. Livieri[3]

Abstract

We used radio-telemetry data (28,560 positional fixes) collected on 153 black-footed ferrets (*Mustela nigripes*) to (1) reexamine the assumed obligate relationship of these ferrets to prairie dogs (*Cynomys* spp.), (2) investigate habitat preferences of ferrets at a small scale (<1 ha), and (3) gain insight into competition among ferrets for habitat patches of varying quality. We used densities of prairie dog burrows as an indicator of habitat quality because burrows are presumably valuable to ferrets as cover and because density of burrows is correlated to density of prairie dogs. Burrow density summaries were generated from maps of all burrows on ferret reintroduction sites in Montana and South Dakota. Aboveground movements by ferrets were mostly (89 percent) within the boundaries of prairie dog colonies or associated with circuits involving return to a colony (10 percent), with no evidence that ferrets sought to occupy alternative habitats. Sampling with 0.07-ha plots suggested that dispersion of prairie dog burrows within colonies was neither uniform nor random. Burrows were clumped, and ferrets preferred ($P < 0.001$) patches of habitat with high densities of burrows compared to samples taken at random points on the colonies they occupied. The magnitude of preference (the difference between use and availability) was greatest for resident young ferrets compared to their recently released counterparts, whether the newcomers were compared with residents of 2–4 weeks ($P = 0.039$) or >1 year ($P = 0.048$). Also, preference was stronger for wild-born young ferrets than for young captive-born ferrets released to augment the wild population ($P = 0.040$). This additional evidence for competition among ferrets, and for an advantage of prior residency, raises conservation concerns. The energetics-based model commonly used to predict ferret densities at reintroduction sites does not consider competition, which likely leads to overestimation of the densities of ferrets attainable in high-quality habitat. During sequential releases of ferrets, prior residency may handicap success of newcomers, even though the latter may have higher potential fitness. Although the manner of initial colonization of available habitat by black-footed ferrets, and their subsequent competition for it, was suggestive of an ideal despotic distribution, we did not assess effects of prey density or burrow density on fitness.

Keywords: black-footed ferret, competition, *Cynomys*, endangered species, habitat, ideal despotic distribution, ideal free distribution, *Mustela nigripes*, prairie dog, prior residency

Introduction

Conservation efforts for the highly endangered black-footed ferret (*Mustela nigripes*) include a captive breeding program that rescued the species from a remnant population of 10 animals in Wyoming (fig. 1) during the winter of 1985–86. That captive breeding program currently produces annual surpluses of 200–300 kits for reintroduction (Marinari and Kreeger, this volume). Ferrets have been reintroduced at sites in six U.S. States and Chihuahua, Mexico (Lockhart and others, this volume). Releases of ferrets into unoccupied and occupied habitat, and monitoring of wild-born ferrets, provided unique opportunities to evaluate large-scale habitat

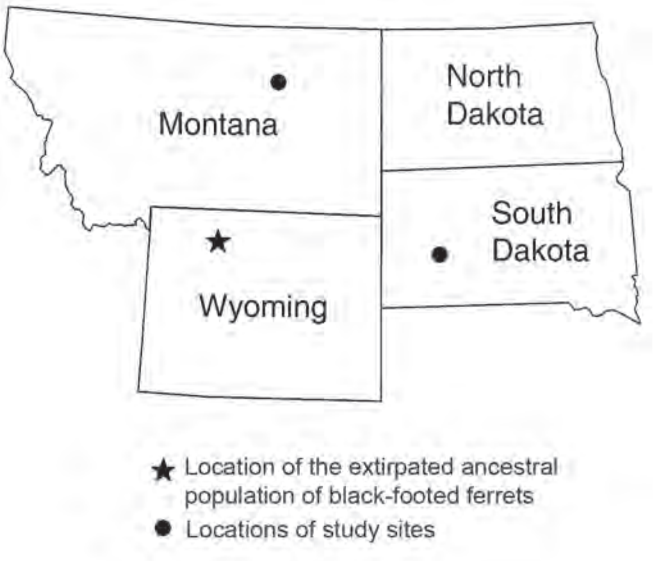

Figure 1. The site near Meeteetse, Wyo., that provided ancestral stock for the captive breeding program, and study sites in Montana and South Dakota where black-footed ferrets (*Mustela nigripes*) were released.

use by ferrets (objective 1), habitat preferences at small scales (objective 2), and relationships between ferret territoriality and habitat quality (objective 3), all of which are relevant to ferret conservation.

Considerable evidence supports a strong relationship between prairie dogs (*Cynomys* spp.) and black-footed ferrets. A summary by Anderson and others (1986) indicates that almost all recent ferret specimens were collected from areas within the composite ranges of black-tailed prairie dogs (*C. ludovicianus*), white-tailed prairie dogs (*C. leucurus*), or Gunnison's prairie dogs (*C. gunnisoni*), and most of the explicit descriptions of locality, where provided, mentioned prairie dog colonies. The last extant ferret populations were found on prairie dog colonies, and studies of those ferrets revealed intensive use of prairie dog colonies (Hillman and others, 1979; Biggins and others, 1985). Prairie dogs are the predominant prey taken by black-footed ferrets (Sheets and others, 1972; Campbell and others, 1987). Strategies for evaluating black-footed ferret habitat (Linder and others, 1972; Forrest and others, 1985; Flath and Clark, 1986; Houston and others, 1986; Biggins and others, 1993) universally assumed that prairie dog colonies were a primary requirement. Others, however, have questioned the characterization of black-footed ferrets as extremely specialized (Owen and others, 2000). One objective of this study was to further document the use of habitats by ferrets on a large scale, using data from radio tracking and maps of black-tailed prairie dog colonies in Montana and South Dakota, to reexamine the degree of dependence of black-footed ferrets on prairie dogs.

Evaluations of ferret habitat are mostly large scale, conducted on colonies hundreds of hectares in size and on complexes occupying thousands of hectares, leaving the details of how ferrets use their local environments largely unexplored. If black-footed ferrets are obligate predators on prairie dogs and variation exists in densities of prairie dogs and their burrows within their colonies, we predict that intensity of ferret activity will correlate positively with density of prairie dogs when habitat is examined at scales smaller than colonies. Thus, our second objective was to evaluate preferences of ferrets by using sample parcels of land <1 ha in size. To address small-scale habitat preferences and the following objective, we used burrow densities as an indicator of habitat quality. Prairie dog burrow densities should give a suitable measure of habitat quality for black-footed ferrets, in part because they correlate to density of the prairie dog prey (Biggins and others, 1993) and in part because burrows have intrinsic value to ferrets as refuges from predators and adverse weather and as dens to rear young.

Black-footed ferrets, like many other mustelids, appear to be intrasexually territorial (Powell, 1979; Miller and others, 1996). In typical carnivore fashion, females attempt to control access to food resources, while males attempt to control access to females (Ewer, 1973). Although several factors in varying combinations appear to contribute to an organism's resource holding power (e.g., relative size of contestants, age, experience in former contests), prior residency often confers significant advantages. The residency advantage is widespread among several taxa, including insects (Davies, 1978), arachnids (Riechert, 1978), decapods (Jennions and Backwell, 1996), fish (Harwood and others, 2003), amphibians (Mathis and others, 2000), and mammals (Neumann, 1999). Because many of the ferrets we studied were released into unfamiliar terrain that was either unoccupied by ferrets or occupied by ferrets for known periods of time, it was possible to examine the effect of prior residency.

Release of ferrets into vacant habitat allowed us to assess the sequence of occupancy. If habitat patches are heterogeneous, the order in which they become colonized or abandoned should relate to quality of those patches as perceived by occupants (Wiens, 1976; Krohn, 1992). Ideal free distribution theory predicts such an interrelationship between population density and carrying capacity of patches in heterogeneous habitats (Fretwell and Lucas, 1970). If order of occupancy reflects quality of habitat patches, then assessment of the colonization process also may lead to improved understanding of source-sink dynamics after habitats become fully populated (Howe and others, 1991; Pulliam and Danielson, 1991). To evaluate intraspecific competition for habitat and order of occupancy of habitat patches, we again utilized radio-telemetry data, overlaying ferret locations onto digitized maps of prairie dog burrows within the colonies studied.

Methods

We radio tracked 153 black-footed ferrets on prairie dog colonies at UL Bend National Wildlife Refuge, Mont., and on the Buffalo Gap National Grassland, S. Dak., during September–November 1994–97 (figs. 1 and 2). Some of the resulting 28,560 telemetric fixes were used for multiple studies; the UL Bend data from 1994 and 1995, for example, were also used in the comparisons of adults and kits reported herein (Biggins, Godbey, Livieri, and others, this volume). We affixed transmitters having 20-cm whip antennas to wool collars of 1-cm width, using Teflon® (DuPont, Wilmington, Del.) heat-shrink tubing (Biggins and others, 1999; Biggins, Godbey, Miller, and Hanebury, this volume). We weighed and radio collared ferrets that were wild caught or captive bred (while the animals were held under isoflurane anesthesia) and inserted passive integrated transponder chips for long-term identification (Biggins, Godbey, Matchett, and others, this volume). Ferrets from captive breeding facilities were reared under a variety of strategies and released during August–November with no more than 1-day acclimation in onsite cages (Biggins and others, 1998).

We radio tracked ferrets from fixed stations fitted with dual-beam, 11-element Yagi antennas on 6-m masts and used null-peak direction finding and triangulation to fix each ferret's position at intervals of 7–60 minutes while the animals

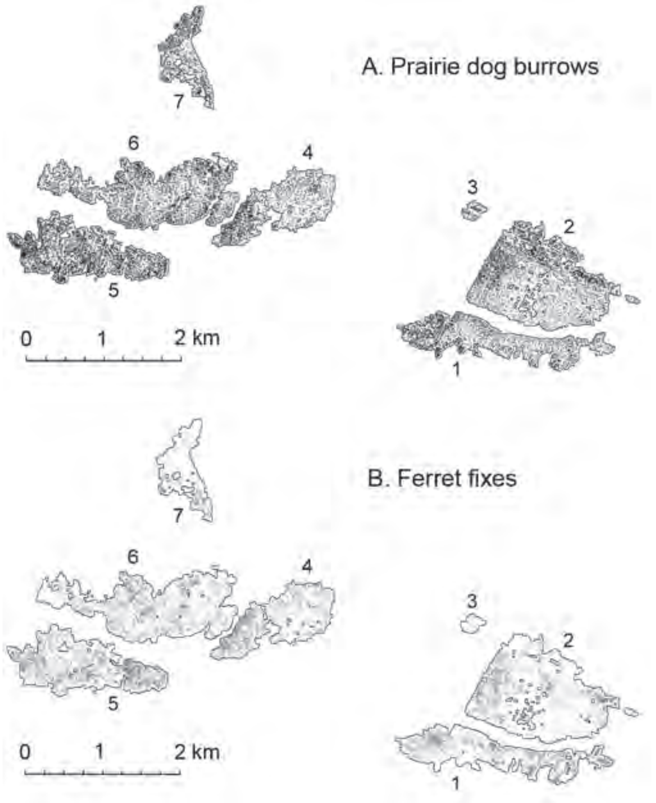

Figure 2. Distribution of black-tailed prairie dog (*Cynomys ludovicianus*) burrows (A) and black-footed ferret (*Mustela nigripes*) telemetric fixes (B) on colonies at UL Bend National Wildlife Refuge, Mont. Each dot is a burrow opening or telemetric fix; density of resulting stippling thus reflects density of burrows or fixes. Attributes for numbered colonies are summarized in table 1.

were active above ground (Biggins and others, 1999; Biggins, Godbey, Livieri, and others, this volume). We developed station-specific error estimates from test data by using differences between telemetry-derived azimuths and azimuths to transmitters of known location (Biggins and others, 1999; Biggins, Godbey, Miller, and Hanebury, this volume). Aboveground activity of black-footed ferrets is mostly nocturnal (Biggins and others, 1986; Biggins, 2000), so we limited monitoring of ferrets to hours of darkness for 2 weeks to 2 months postrelease. We recorded estimated locations of ferrets and associated error polygons as Universal Transverse Mercator coordinates derived from paired azimuths with program TRITEL (Biggins, Godbey, Miller, and Hanebury, this volume).

We recorded locations of prairie dog burrow openings (henceforth, such openings will be referred to as burrows) with Global Positioning System (GPS) receivers, differentially corrected to provide point estimates with errors of <1 m. ArcInfo® Version 8.2 (Environmental Systems Research Institute, Inc., Redlands, Calif.) was used for all vector processing, and the GRID module was used for all raster modeling. The vector point data for all prairie dog burrows and ferret locations in the study were consolidated into the Universal Transverse Mercator Zone 13 projection using the North American Datum of 1927. The GRID module was used to convert the vector points to 1-m^2 cells. To create a map of each prairie dog colony, cells were expanded by 10 m in every direction. Thus, the maps of colonies (fig. 2A,B; table 1) can be envisioned to include a buffer of 10 m beyond the outermost burrows and to exclude spaces within the outer boundary that are >10 m from the nearest burrow.

Use of Habitats Other than Prairie Dog Colonies

To investigate the broad-scale preference of black-footed ferrets for prairie dog colonies, we examined ferret use of the colonies as defined above and their use of noncolony areas. Ferret fixes were classified as being on or off colonies. Because there were nearby colonies in the South Dakota complex that were not mapped with the system described, ferret fixes that were not on mapped colonies could have been on other colonies. Thus, we did not use South Dakota data for these large-scale assessments. Similarly, a subset of ferrets in Montana (14 animals living near the eastern boundary of the subcomplex) had access to colonies that were not mapped with this system and were likewise eliminated from the analysis. The remaining data used for this overview included 24,512 fixes on 108 radio-tagged animals, including released and resident adults and kits. Because ferrets presumably must make exploratory moves to assess the distribution of prairie dogs, and because some ferrets traversed noncolony areas during routine travels between colonies, fixes that were off colonies do not necessarily imply that ferrets were actually living in areas not occupied by prairie dogs. We estimated the relative use of noncolony areas attributable to these phenomena, defining an off-colony excursion as a movement involving ≥2 fixes

Table 1. Black-tailed prairie dog (*Cynomys ludovicianus*) colonies where prairie dog burrows were mapped. Numbers for Montana colonies correspond to the numbered colonies of figure 2.

Colony	Area (ha)	Burrows/ha
Montana		
1. South Locke	90.1	57.9
2. North Locke	166.0	48.9
3. Small	5.0	64.1
4. Sagebrush	79.8	49.8
5. South Hawley	102.4	79.4
6. North Hawley	144.0	54.6
7. Wilderness	42.2	62.1
South Dakota		
North Sage Creek	160.1	138.9

away from a colony, followed by return to a colony. We also tallied the number of fixes associated with intercolony moves and dispersal moves (movement with no return to a colony).

Preferences Within Prairie Dog Colonies

We examined habitat preferences of ferrets within colonies at a small scale by comparing counts of the number of mapped burrows in circular plots of 0.07 ha (radius = 15 m) surrounding ferret fixes with counts in similar plots surrounding random points on colonies (fig. 3), sampling with replacement (plots were allowed to overlap). To be included in the analysis, the boundary of a sample plot was required to be entirely within a colony as defined above. Ferrets with ≤3 fixes were excluded. To characterize densities of prairie dog burrows on the Montana colonies, we sampled 20,328 plots at random points and compared those to plots centered on 21,185 fixes for 110 ferrets. In South Dakota, we counted burrows within plots surrounding 427 fixes (for 19 ferrets) and 465 random points. Because many ferret fixes for individual animals were serially autocorrelated (e.g., the sequential fixes of fig. 3), we summarized density of burrows within plots as mean densities for each animal and used those means in all subsequent analyses. Thus, sample sizes became numbers of animals (not numbers of fixes). We further restricted this data set to include only those ferrets radio tracked >3 days; estimates for animals radio tracked for shorter periods were deemed unreliable.

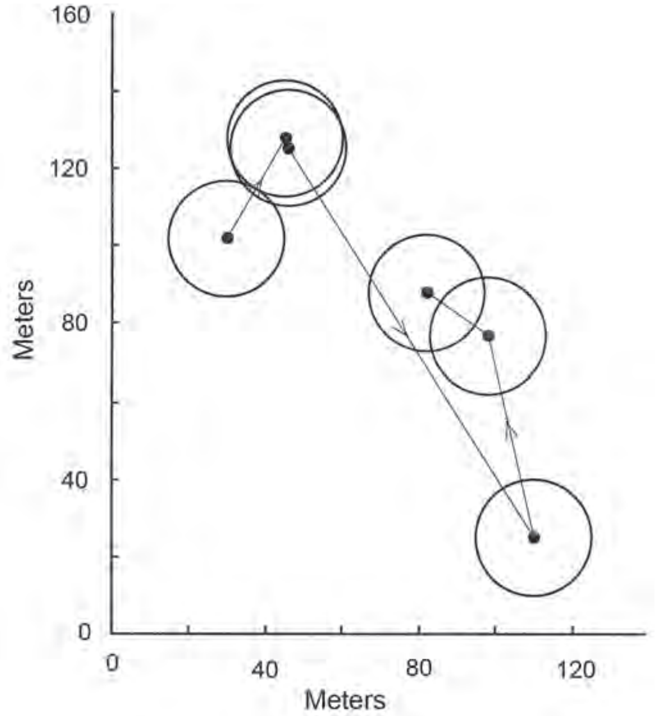

Figure 3. Example of encircling a series of telemetric fixes with plots of 15-m radius, within which black-tailed prairie dog (*Cynomys ludovicianus*) burrow entrances were counted, for black-footed ferret (*Mustela nigripes*) no. 32, North Sage Creek, S. Dak., on the night of October 26–27, 1997. Overlapping plots were allowed for both ferret fixes and random points (sampling with replacement).

A patchy distribution of habitat (burrows) within prairie dog colonies is a prerequisite for allowing choice by ferrets. Frequencies of counts within the plots described above would be expected to follow a Poisson distribution if dispersion of burrow openings on colonies were random (Ricklefs, 1990). For a Poisson distribution, the variance in counts is equal to the mean; evenly spaced burrow openings will produce a variance less than the mean, and clumped burrow openings will result in variance greater than the mean. We examined the variance:mean ratios for the counts within our samples of circular plots to provide an indication of dispersion of burrow openings in each colony.

Intraspecific Competition for Habitat

To assess intraspecific competition for habitat, we compared habitats occupied by groups of black-footed ferrets that were expected to differ in competitive standing. We predicted that (1) resident adult ferrets would have a competitive advantage over their wild-born kits, (2) wild-born kits would have an advantage compared to released kits, (3) kits released first would be more competitive than kits released subsequently into the same area in the same year, (4) larger kits would have an advantage over smaller kits, and (5) kits released into unoccupied habitat during the first year of reintroductions at a site would have an advantage over kits released in subsequent years to augment a population. As outlined above, we assumed burrow density correlated positively with habitat quality. We thus expected dominant ferrets to occupy areas of higher burrow density compared to their less competitive counterparts. We assessed burrow densities estimated from the sample of 0.07-ha plots described above.

As implied by the groups in comparisons 1–5 above, various overlapping subsets of animals were used for analyses. Montana data were best suited for this assessment because ferrets were released in multiple years on several colonies, they were released in several consecutive groups in the same colonies during 2 years, and resident ferrets were monitored during 1 year. As with the broader analysis above, we included only those ferrets radio tracked >3 days. Within the Montana data set, the comparison of adult and young resident ferrets (1 above) was limited to the 1997 subset of data collected on Hawley and associated colonies, as was the comparison of wild-born and released young ferrets (2). We compared groups of young ferrets released sequentially during the same years at the same sites (3) within the 1994 and 1995 data sets at all colonies. Measures of mass (4) were available for Montana animals released in 1994 and 1995, and that variable was included in the assessment of within-year sequential releases. Because sexes are dimorphic, we included sex in the model to interact with mass. Finally, we compared young ferrets released into vacant habitat at Hawley and associated colonies in 1995 with young ferrets released into that habitat in 1997, when portions of it were occupied by resident ferrets (5 above). That 368.3-ha area of prairie dog colonies (the four western colonies of fig. 2A,B) was occupied by at least 8 adults and 19 kits that we marked (not all were monitored via the radio tracking of this study).

To provide additional evidence on the effect of competition, we assessed numbers of released ferrets that moved between colonies in 1995, when these ferrets were released into habitat without a resident population of ferrets, and in 1997, when ferrets were released into the same prairie dog colonies to augment an existing population.

Statistical Evaluation

For statistical comparisons, we reduced burrow density data to animal-specific estimates for habitat they used, paired with colony-specific estimates for colonies they occupied. If an animal occupied more than one colony, we calculated separate pairs of estimates (use and availability) for each colony. We used multivariate general linear modeling (repeated measures) to evaluate differences between burrow densities for colonies and for habitat used by ferrets, assuming that all habitat on the colony occupied by a ferret was potentially available to that ferret. General models were reduced to more parsimonious versions by backward elimination using partial *F*-tests, when appropriate. Comparisons were judged as significant if the probability of committing a Type I error was ≤0.05. Exact chi-square analyses (Berry and Mielke, 1985) assisted in evaluation of proportions of ferrets engaging in intercolony movements.

Results

Use of Habitats Other than Prairie Dog Colonies

Of the 24,512 total fixes used, 2,744 (11.19 percent) were off colonies. There were 88 instances of intercolony movement. Some of the off-colony locations were solitary telemetric fixes that could be the result of radio-tracking error. Because clusters of sequential fixes provide information on pattern of movement, we assessed off-colony moves using groups of ≥2 consecutive fixes away from a colony. The number of clustered fixes off colonies was 2,010 in 474 bouts of movement made by 87 animals with 1 to 24 bouts per ferret; 1,767 of these (87.91 percent) were associated with exploratory excursions involving returns to the colony of origin (fig. 4) and intercolony moves (fig. 5). If these cluster-based estimates are applied to the total of 11.19 percent of fixes away from prairie dog colonies, it appears that only about 1.4 percent (0.1119 * 0.1209 = 0.0135) of the total number of off-colony fixes may involve dispersal (fig. 6) without known return to the colony of origin or travel to another colony.

Preferences Within Prairie Dog Colonies

Patchiness in dispersion of burrow openings was highly evident, as indicated by variance:mean ratios >>1.0 for all colonies (fig. 7) sampled by 0.07-ha circular plots. Overall, black-footed ferrets preferred patches of habitat with densities of prairie dog burrows higher than the averages for colonies they occupied (fig. 8). Our general statistical model evaluated overall differences between ferret plots and random plots (hereafter referred to as preference) and the effects of sex and colony. Sex accounted for relatively little variation ($F_{1,149}$ = 0.130, P = 0.719) and was removed from the model. Preference of sites with elevated densities of burrows was consistent ($F_{1,154}$ = 16.996, P < 0.001) among colonies (fig. 8), but the magnitude of the differences between burrow densities in

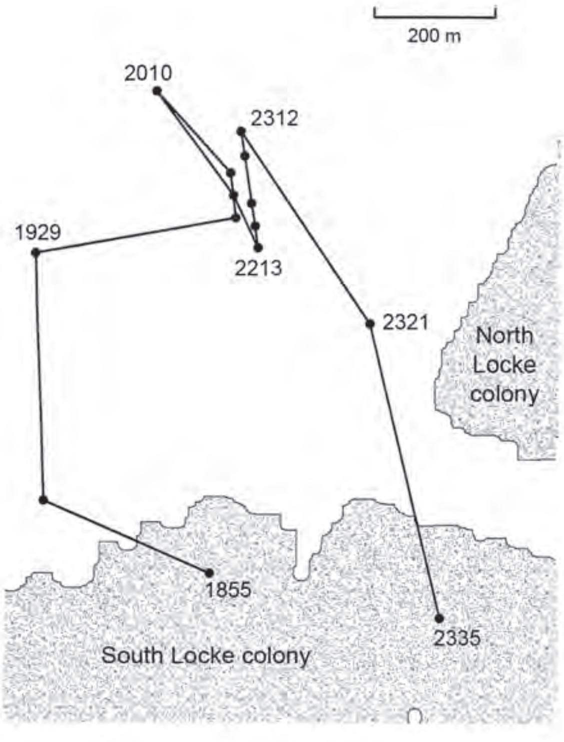

Figure 4. An example of an exploratory excursion away from a black-tailed prairie dog (*Cynomys ludovicianus*) colony by young male black-footed ferret (*Mustela nigripes*) no. 24, UL Bend National Wildlife Refuge, Mont., October 20, 1994. Numbers associated with points are times of day.

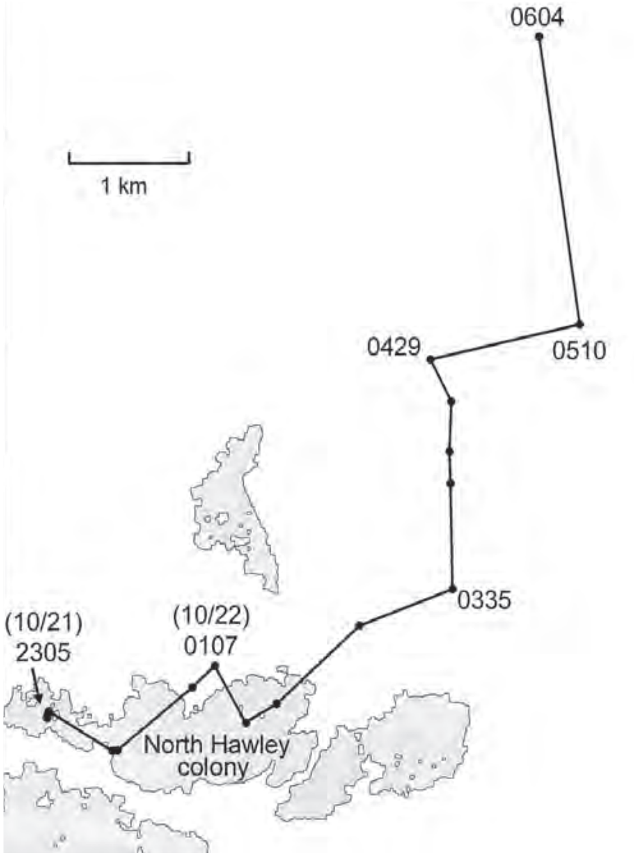

Figure 6. An example of dispersal away from black-tailed prairie dog (*Cynomys ludovicianus*) colonies by young male black-footed ferret (*Mustela nigripes*) no. 213, October 21–22, 1997. Numbers associated with points are times of day.

ferret and random plots appeared to vary (preference × colony interaction; $F_{7,154} = 2.144$, $P = 0.042$).

Intraspecific Competition for Habitat

Three of the four general models in these analyses had only class of animal in the repeated measures comparison of random and ferret-centered estimates of burrow density; these three models were not further reduced. Failure of sex and mass (in the 1994 and 1995 Montana data) to explain significant variation ($P > 0.160$) resulted in reduction of that model to a simpler submodel resembling the others used to evaluate competition. Each of these subsets of data reflected the significant habitat preferences of ferrets ($P \leq 0.010$) that were documented in the more general treatment above. Our primary focus in evaluations of competition was centered on the interaction term of each model that tested whether classes of ferrets influenced variation in differences between habitat used and habitat available (preference). In that regard, only the comparison between habitat preferences of resident adult ferrets and their resident young failed to explain significant variation (preference × age interaction; $F_{1,31} = 0.579$, $P = 0.452$). As predicted, wild-born resident young ferrets were

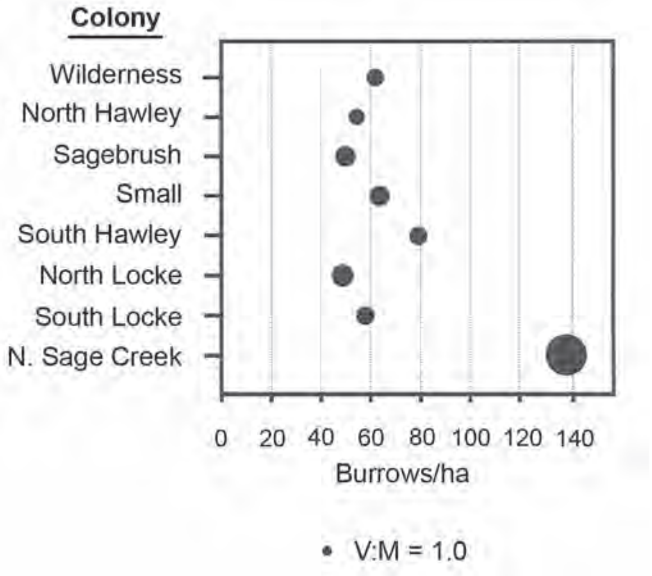

Figure 7. Densities of burrows on study colonies and variance to mean ratios (V:M) estimated from samples of 0.07-ha plots. Diameter of symbol is proportionate to V:M ratio within sample of plots.

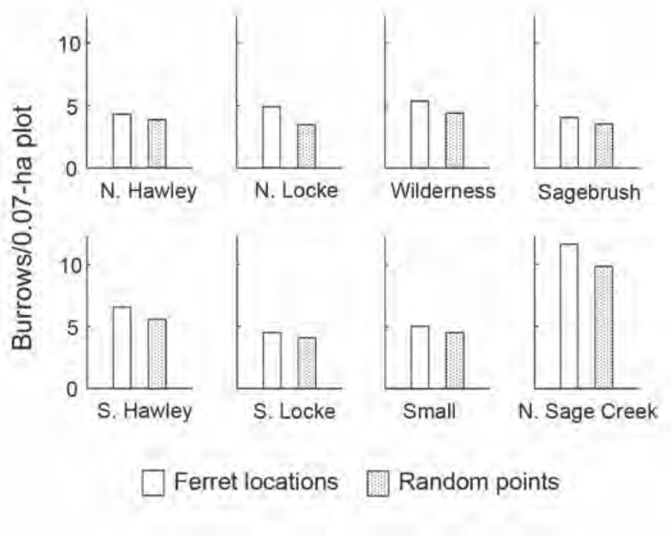

Figure 8. Burrow densities within plots encircling telemetric fixes of black-footed ferrets (*Mustela nigripes*) and within plots at random points on black-tailed prairie dog (*Cynomys ludovicianus*) colonies.

able to exercise a higher level of preference than did released young (fig. 9) (preference × origin interaction; $F_{1,51}$ = 4.445, P = 0.040), first-released young ferrets were more selective than were young released later the same year (fig. 10) (preference × sequence interaction; $F_{1,67}$ = 4.430, P = 0.039), and young ferrets released into vacant habitat were more selective than were young used to augment the population in that habitat during a later year (fig. 11) (preference × year interaction; $F_{1,62}$ = 4.063, P = 0.048).

Most (12/13 = 92.3 percent) young ferrets added to the resident population in the western colonies of the UL Bend complex in 1997 moved between colonies. That proportion was significantly different (X^2 = 13.789, df = 1, P < 0.001) from the corresponding proportion for 1995 (8/27 = 29.6 percent), when young ferrets were released into the same colonies that were then vacant.

Discussion

Use of Habitats Other than Prairie Dog Colonies

The term “preference” suggests that use is compared to availability, but we made no explicit attempt to define or measure availability of habitat not occupied by prairie dogs. Noncolony areas, however, were much more available to ferrets (on a large scale at least) than were prairie dog colonies. Thus, the extremely high use of prairie dog colonies by black-footed ferrets does indeed suggest strong preference, and there was no need to delve into more rigorous analyses of preference at that large scale.

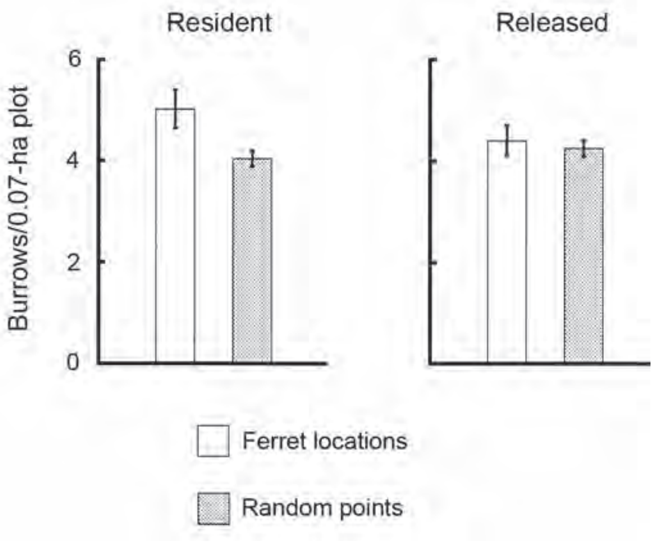

Figure 9. Densities of burrows (mean ± SE) in areas used by (and available to) black-footed ferret (*Mustela nigripes*) kits released into ferret-occupied habitat at Hawley Flats Mont., in 1997, and densities of burrows in habitat used by (and available to) the resident wild-born ferret kits at that site.

Figure 10. Densities of burrows (mean ± SE) in areas used by (and available to) the first black-footed ferret (*Mustela nigripes*) kits released at Locke Ranch and Hawley Flat, Mont., in 1994 and 1995, and densities of burrows in areas used by (and available to) ferret kits after subsequent releases during those years at those sites.

Most ferrets tracked during this study were young of the year, and many were captive-born ferrets released onto prairie dog colonies. To learn about their new surroundings, these naive animals must explore, and some may adopt home ranges that include multiple colonies. Thus, the small proportion of telemetric fixes away from prairie dog colonies is mostly explained by behaviors that should be expected even for a species fully dependent on prairie dogs. Also, a greater proportion of off-colony fixes occurred in the 1997 animals

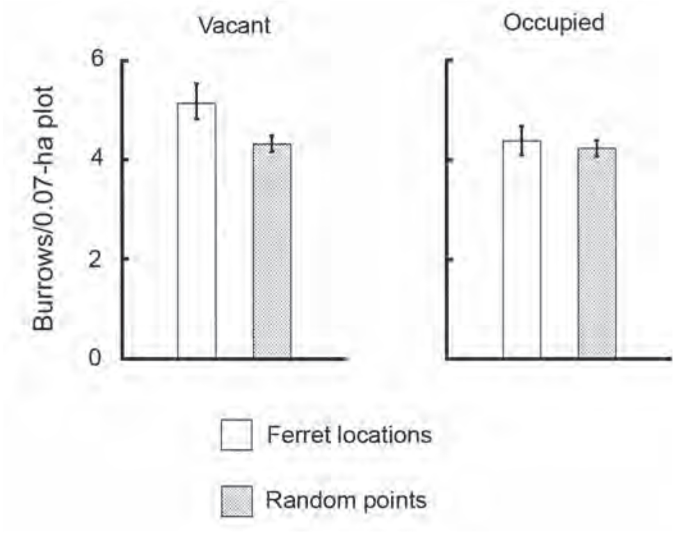

Figure 11. Densities of burrows (mean ± SE) in areas used by (and available to) black-footed ferret (*Mustela nigripes*) kits released into ferret-unoccupied habitat at Hawley Flat, Mont., in 1995, and densities of burrows in areas used by (and available to) ferret kits released to augment the extant population in 1997.

(16.7 percent), which were subjected to potentially more intense intraspecific competition than were the ferrets released into unoccupied habitat in 1994 and 1995. Considering that the remaining small proportion of "unexplained" off-colony moves also involved (1) ferrets that were killed by predators and carried away from colonies, (2) ferrets with whom telemetric contact was lost, rendering their future travels and fates unknown, (3) predominantly captive-reared ferrets that may behave erratically at times, and (4) dispersal that ultimately may lead ferrets to other prairie dog colonies, there was little indication that ferrets will attempt to live on habitat other than prairie dog colonies, let alone successfully colonize other habitats. We documented a high degree of preference for prairie dog colonies by ferrets, which weakens the contention that there should be a "broader range of possibilities for conservation of the black-footed ferret" (Owen and others, 2000, p. 422), an argument implying broader habitat tolerances based on similarities between black-footed ferrets and Siberian polecats (*Mustela eversmannii*) and the hypothetical niches of North American Pleistocene and Holocene ferrets (or polecats). Our data and those of others (e.g., Biggins, 2000) suggest that natural selection has resulted in considerable divergence of behaviors and nonskeletal features in these two extant species of *Mustela* and that they are "ecological equivalents" (Hoffman and Pattie, 1968, p. 57; Lincoln and others, 1998, p. 94) only in the broadest sense. Attempts to release each species on varying habitats further test this hypothesis. Reproductively sterile Siberian polecats persisted for only short periods when released on prairie dog colonies in Wyoming (16 percent survival for 15 days) and Colorado (16 percent survival for 1 day) (Biggins, 2000), and some of the polecats used habitats other than the prairie dog colonies. Release of Siberian polecats and black-footed ferrets into colonies of larger species of North American ground squirrels (*Spermophilus*) has not been attempted but could be informative.

Preferences Within Prairie Dog Colonies

For analyses of habitat preference within colonies, we defined as available to a ferret all of the prairie dog colony on which it resided. Definitions of availability are always somewhat arbitrary but are important because they affect the outcome of preference analyses (Johnson, 1980). Prior studies of ferret movements (Biggins and others, 1985, 1999; Biggins, 2000), coupled with the relatively small sizes of the colonies of the present study, helped justify our definition. We believe that the subjects of our study would not have been physically impeded from accessing any portion of the colonies on which they resided and were influenced primarily by the variables targeted for study (quality of habitat and competition for it). Even within the boundaries of prairie dog colonies, therefore, ferrets consistently preferred areas with relatively high densities of prairie dog burrows.

The preference of black-footed ferrets for areas on prairie dog colonies with high densities of prairie dog burrows was made possible by the clumped dispersion of burrows at our study sites. This nonrandom and nonuniform arrangement of burrow openings may be due to phenomena at several scales. Habitat quality for prairie dogs themselves may vary within the boundaries of their colonies, resulting from variation in soil type, soil depth, slope, and aspect. Vegetative mosaics are apparent on some colonies, resulting from these edaphic and physiographic attributes and other influences (e.g., plant competition) and from grazing by prairie dogs. Thus, the patchiness we observed at the scale of our plots (707 m^2) is likely a reflection of the patchiness at intermediate scales (measured in hectares) resulting from the factors mentioned above coupled with variation at finer scales caused (at least in part) by the social organization of black-tailed prairie dogs into coteries and by interconnected burrow openings within coteries (Hoogland, 1995). We believe that attention to these considerations of scale will be increasingly important in gaining a more complete understanding of ferret ecology. Former evaluations of habitat for black-footed ferrets (e.g., Hillman and others, 1979; Forrest and others, 1985; Houston and others, 1986; Miller and others, 1988; Biggins and others, 1993) heavily emphasized the larger scales of colonies and complexes and may have led us to overlook details important to ferrets. Ferret preferences for areas of relatively high densities of prairie dog burrows, and the apparent intraspecific competition for those areas, imply qualities that may be related to fitness. We hypothesize that the value of clusters of burrow openings lies not only in their correlation to clusters of prairie dogs as prey but also in the immediacy of protective cover from predators during aboveground movements by ferrets. Predation appears to be a substantial hazard for ferrets (Forrest and others, 1988; Biggins, 2000), causing by far the most losses during the repatriation program (Biggins, Godbey, Livieri, and others, this volume). Because of the positive association between safety and resources, ferrets are not forced into tradeoffs requiring choices between “a productive, but risky habitat and a less productive, safer habitat” (Grand and Dill, 1999, p. 389).

Intraspecific Competition for Habitat

Several lines of previous evidence suggest that territoriality is an important feature in the social lives of black-footed ferrets. Although direct agonistic encounters between free-ranging individual ferrets are rarely seen (Clark and others, 1986), two adult males were observed in what was described as “mortal combat” at the UL Bend in 1997 (Stoneberg, 1997, p. 13). Play behaviors in juveniles that may be precursors to such behaviors in adults (Poole, 1966, 1967, 1974) were commonly seen in free-ranging (Hillman, 1968; Clark and others, 1986) and captive (Miller, 1988; Vargas, 1994) litters. Agonistic behaviors between captive adult black-footed ferrets resembled agonistic interactions of domestic ferrets (Miller, 1988). General spacing patterns suggest that ferrets occupy somewhat distinct territories (Clark, 1989). Scent marking is a common behavior in ferrets and is particularly evident for males during the breeding season (Miller, 1988). Our understanding of competition among ferrets (especially females) for resources or space is nevertheless incomplete. Although free-ranging ferrets tend to occupy space that is not used by other ferrets of the same sex, occasional sharing of space by females during winter (Richardson and others, 1987) and even by females with litters (Paunovich and Forrest, 1987) raises doubts about exclusiveness of areas of activity. Captive Siberian polecats have been held in large cages for prolonged periods as same-sex and mixed-sex groups, but, on other occasions, aggression has been immediate and severe when multiple polecats were introduced into the same space (D. Biggins, unpub. data, 1995). Individual black-footed ferrets have severely injured their neighbors in conflicts through the wire mesh that separated their adjacent outdoor pens, and female ferrets have even killed their prospective mates (A. Vargas, oral commun., 1995). Simple rules seem inadequate for predicting outcomes of interactions. For females especially, activity area sizes and their exclusivity in time and space may be influenced by habitat quality and variation among individuals (Biggins, 2000), and perhaps nepotism at times masks the central tendency of ferrets to defend territories.

Nonetheless, the general theme of competition among black-footed ferrets for possession of space was supported by our study; the group that was predicted to be subordinate based on prior residency consistently occupied the habitat of lower quality. Large body size may be an advantage in contests, but we did not detect a significant effect of mass in the competition for high-quality habitat among sequentially released young ferrets. Ferrets seemed to follow the “bourgeois strategy” (Ramsay and Ratcliffe, 2003, p. 120) in which prior residency overwhelms effects of size and other factors. The duration of prior residency also may have an effect (Harwood and others, 2003). In an experiment involving releases of white-throated sparrows (*Zonotrichia albicollis*) into outdoor aviaries, Dearborn and Wiley (1993) noted a gradual increase in effect of prior residency from 2–45 days, but the increase was most dramatic during the first 14 days. Duration of prior residency for ferrets in our sequential release experiment was fairly brief, with 2–4 weeks between the first and subsequent releases, but duration of residency was >1 year for individuals in the extant population that was augmented in 1997.

As ferret populations are assembled through progressive releases and additions of wild-born animals, intraspecific competition appears to result in sequential occupation of habitat patches by descending order of burrow (and prey) density. As available habitat becomes filled, the additional occupancy of sites with lower densities of burrows and prairie dogs is expected to increase the variance in burrow density of occupied sites. At sites with low burrow densities, areas of activity of ferrets may be largest. These phenomena outwardly resemble the characteristics associated with an ideal free distribution or an ideal dominance (despotic) distribution (Fretwell and Lucas, 1970). Explorations by released ferrets may be sufficient to impart “ideal” knowledge regarding availability of habitat, but territoriality of resident ferrets may prevent “free” choice (sensu Fretwell and Lucas, 1970). Further assessment of processes involved in ferret habitat occupancy in relation to theoretical distributions (Fretwell and Lucas, 1970; Fretwell, 1972) must consider relative fitness (Messier and others, 1990; Beckman and Berger, 2003), a topic we will address separately with other data sets.

Commonly used habitat evaluation systems for black-footed ferrets (e.g., that of Biggins and others, 1993) likely overestimate ferret densities attainable on the best habitats. As acknowledged by Biggins and others (1993, p. 75) in the introduction to their suggested model, “Social behavior may dictate a maximum ferret density regardless of prey abundance.” Mounting evidence regarding territoriality in ferrets does indeed suggest that models used to predict carrying capacity of habitat for ferrets should include an increasing effect of social exclusion of ferrets at high densities of prairie dogs. Because the best quality habitats as rated by the model of Biggins and others (1993) are presently sustaining ferrets at densities almost double those of low-quality habitats, we suggest retention of the fundamental structure of the model, with modifications recently suggested (Biggins, Lockhart, and Godbey, this volume). Although our comparative data suggest that competitiveness varies among individuals and has an important influence on population assembly (groups varied in their ability to control space and resources), we are unable to estimate the strength of territoriality at varying prey densities.

Additional studies on territoriality in male and female ferrets could help refine predictions of the model at high prairie dog densities. The model also would benefit from an improved understanding of habitat limitations for reproductive female ferrets inhabiting colonies with low prairie dog densities, a subject beyond the scope of this study.

The prior residency advantage raises other issues of conservation concern. Quality of ferrets released may vary because of prerelease experience (Biggins and others, 1998, 1999) and age (Biggins, Godbey, Livieri, and others, this volume). Preliminary releases of lower quality animals may reduce the amount of good habitat available for higher quality animals subsequently released if the first animals become established. Even if those first residents succumb rather quickly to predation, their initial presence could elevate the risk to newcomers during the first critical days postrelease. Thus, we recommend careful consideration be given to choice of sites and sequence of release when habitat will receive groups of ferrets varying in prerelease experience, origin, and age.

Acknowledgments

Although space prevents us from individually recognizing the more than 40 technicians who radio tracked black-footed ferrets during these studies, we are grateful for their dedication to those long hours of nocturnal monotony punctuated with brief bouts of pandemonium. Funding was provided by the Legacy Program of the U.S. Department of Defense; U.S. Fish and Wildlife Service (FWS); U.S. Forest Service; U.S. Geological Survey; Montana Department of Fish, Wildlife and Parks; National Biological Service; National Fish and Wildlife Foundation; National Park Service; South Dakota Department of Game, Fish and Parks; U.S. Air Force; U.S. Army; and Wildlife Preservation Trust International (now Wildlife Trust). We appreciate the assistance from Project Lighthawk in moving ferrets from Pueblo, Colo., to Montana. We are deeply indebted to those who raised black-footed ferrets for the reintroduction efforts, including individuals at the Black-footed Ferret Conservation Center (FWS and Wyoming Game and Fish Department), National Zoo, Henry Doorly Zoo, Louisville Zoo, Phoenix Zoo, Toronto Zoo, Cheyenne Mountain Zoo, and the Pueblo experimental rearing facility (FWS). Additional efforts were required by dedicated individuals who preconditioned ferrets at F.E. Warren Air Force Base, Wyo., and Buffalo Gap National Grassland, S. Dak. We appreciate the assistance of B. Waltermire and D. Schneider with GIS analysis of the prairie dog burrow data. Our generic list of agencies and institutions seems inadequate to acknowledge the hundreds of individuals who accomplished the multitude of tasks necessary to produce these ferrets and move them back to their native habitats. The teamwork and coordination were mind boggling. We extend genuine appreciation to all, admitting that this is a paltry tribute for accomplishment of such a monumentally important task.

Evaluating Habitat for Black-footed Ferrets: Revision of an Existing Model

By Dean E. Biggins,[1] J. Michael Lockhart,[2] and Jerry L. Godbey[1]

Abstract

Black-footed ferrets (*Mustela nigripes*) are highly dependent on prairie dogs (*Cynomys* spp.) as prey, and prairie dog colonies are the only known habitats that sustain black-footed ferret populations. An existing model used extensively for evaluating black-footed ferret reintroduction habitat defined complexes by interconnecting colonies with 7-km line segments. Although the 7-km complex remains a useful construct, we propose additional, smaller-scale evaluations that consider 1.5-km subcomplexes. The original model estimated the carrying capacity of complexes based on energy requirements of ferrets and density estimates of their prairie dog prey. Recent data have supported earlier contentions of intraspecific competition and intrasexual territorial behavior in ferrets. We suggest a revised model that retains the fixed linear relationship of the existing model when prairie dog densities are <18/ha and uses a curvilinear relationship that reflects increasing effects of ferret territoriality when there are 18–42 prairie dogs per hectare. We discuss possible effects of colony size and shape, interacting with territoriality, as justification for the exclusion of territorial influences if a prairie dog colony supports only a single female ferret. We also present data to support continued use of active prairie dog burrow densities as indices suitable for broad-scale estimates of prairie dog density. Calculation of percent of complexes that are occupied by prairie dog colonies was recommended as part of the original habitat evaluation process. That attribute has been largely ignored, resulting in rating anomalies.

Keywords: black-footed ferret, burrows, carrying capacity, competition, *Cynomys*, energy, habitat, *Mustela nigripes*, prairie dog, territory

Introduction

By 1988, captive breeding of black-footed ferrets (*Mustela nigripes*) rescued from a failing population in Wyoming was becoming successful (Biggins and others, 1997), and a subcommittee of the Black-footed Ferret Interstate Coordinating Committee (ICC) addressed the challenge of locating, evaluating, and comparing sites for black-footed ferret reintroduction. Habitat for terrestrial species, including prairie dogs (*Cynomys* spp.), is commonly evaluated with respect to vegetative and physiographic features. Although we recognize the crucial link between prairie dogs and their environments, the extreme specialization of the black-footed ferret allows us to equate black-footed ferret habitat with prairie dog colonies. A habitat model now in common use was developed by the ICC to assess the ability of prairie dog colonies and complexes to support populations of black-footed ferrets (Biggins and others, 1993). The model arose from earlier descriptions and models of ferret habitat (Linder and others, 1972; Hillman and others, 1979; Forrest and others, 1985; Houston and others, 1986; Miller and others, 1988), models of ferret energetics (Stromberg and others, 1983; Powell and others, 1985), data on ferret nutrition and food habits (Sheets and others, 1972; Campbell and others, 1987; Joyce, 1988), and information on behaviors of free-ranging ferrets (Hillman, 1968; Biggins and others, 1985; Paunovich and Forrest, 1987; Richardson and others, 1987). Biggins and others (1993) also provided a method for estimating approximate densities of prairie dogs from strip transect samples of active burrows and offered a technique for grouping colonies into complexes. Complexes were defined as clusters of colonies that could be circumscribed with 7-km line segments; colonies are sequentially added to a complex if they are separated by ≤7 km. Spaces within a complex that are devoid of prairie dogs are defined similarly.

We herein suggest changes to procedures described by Biggins and others (1993), based in part on information collected during 1991–2003 from reintroduced populations of black-footed ferrets, and we discuss aspects of the existing system needing renewed emphasis. Changes include assessing portions of complexes at a smaller scale (called subcomplexes), incorporating the effects of ferret territoriality

in assessments of habitat carrying capacity, and limiting the effect of ferret territoriality on small habitat patches where social strife is unlikely to influence ferret use.

Subcomplexes

The initial impetus for considering smaller, more compact clusters of prairie dog colonies as subcomplexes stemmed from de facto procedures used to select and prioritize ferret release sites. Sites were intuitively regarded as high quality if colonies were closely spaced or large and if prairie dog densities were high. Release of ferrets took place on such "core" sites, with much less attention given to the remainder of the complex as defined by the 7-km procedure (Biggins and others, 1993). We describe a process, involving subcomplexes, that has been in practical use since 1999 by the U.S. Fish and Wildlife Service and partners to allocate ferrets.

On occasion, more than one cluster of colonies has been used as a release site, but ferret releases in each year have been conducted on relatively small portions of complexes. Following initial release(s), ferrets rather quickly populated some of these core release areas through natural reproduction; other clusters in a complex defined with the 7-km criterion were mostly populated with additional releases (e.g., Conata Basin, S. Dak.) or natural dispersal over longer time periods (Shirley Basin, Wyo.). Although lines of delineation are arbitrary, ferret movement within clusters where colonies were separated by ≤1.5 km was common. At UL Bend National Wildlife Refuge, Mont., for example, there were 88 intercolony moves by radio-tagged ferrets during 1994, 1995, and 1997 (Biggins, Godbey, Matchett, and Livieri, this volume); 77 (85.5 percent) of these moves were between colonies separated by <1.5 km, but all moves were between colonies separated by <2.1 km. In the Meeteetse, Wyo., complex of white-tailed prairie dogs (*Cynomys leucurus*) that supported the remnant ancestral population of ferrets, most colonies were interconnected with a 1.5-km maximum distance between them. Based on these experiences and data, we propose defining a subcomplex as a group of colonies that can be linked to one another with a series of line segments ≤1.5 km in length. The procedure for outlining a subcomplex will be further standardized by following the method used to circumscribe a complex (Biggins and others, 1993), but substituting a 1.5-km line segment for the 7-km line segment (fig. 1).

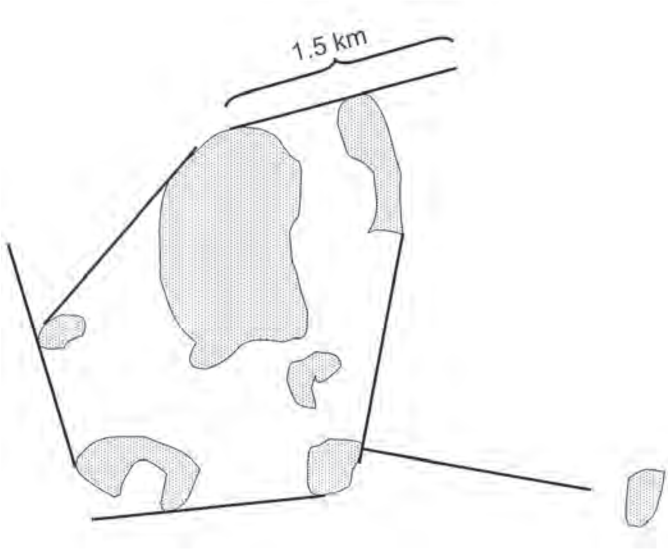

Figure 1. Procedure for circumscribing a subcomplex of prairie dog (*Cynomys* spp.) colonies by using a minimum intercolony distance of 1.5 km. See Biggins and others (1993) for additional details on the methodology.

Territoriality and Carrying Capacity

Carrying capacity has been traditionally discussed in terms of populations of an organism and their food supply, with implications of sustainability of resources (Leopold, 1933). In that sense, the habitat model of Biggins and others (1993) attempts to estimate carrying capacity of prairie dog colonies for black-footed ferrets. Many organisms, however, seem to space themselves within habitat. Carnivores are often intrasexually territorial, but King's (1990) chapter on "adjustable living spaces" provides evidence that there is an interaction between habitat quality (mainly abundance of prey) and territoriality for other *Mustela* species. The utility of estimating the upper limits of habitat to sustain organisms, whether such limits are imposed by food or other mechanisms, was evident in early attempts to model regulated growth with the logistic equation (Pearl and Reed, 1920) and in Leopold's (1933) discussions of managing game for sustained yields. More recent efforts at modeling ferret population fluctuations require similar input (Bevers and others, 1997).

Although somewhat conflicting evidence precluded considering ferret territoriality in their earlier model, Biggins and others (1993, p. 75) suggested that "social behavior may dictate a maximum ferret density regardless of prey abundance." There is increasing evidence that black-footed ferret territoriality does indeed constrain predictions of the energetics model when prey may not be limiting. First, reintroduced ferret populations in South Dakota habitats seldom had average densities exceeding about 1 female per 30 ha, even though the energetics-based model often predicted 1 female per 20 ha or less. Additional evidence from ferrets released in Montana and South Dakota suggests that there is competition for good quality habitat (Biggins, Godbey, Matchett, and Livieri, this volume). These recent results are consistent with observations that female ferrets generally do not use overlapping areas (Richardson and others, 1987) and evidence of spacing in other *Mustela* species (Powell, 1979; King, 1990). The mounting evidence is sufficiently compelling that we here suggest adding a function to the simple linear relationship between densities of black-footed ferrets and prairie dogs that will have increasing impact as ferret density rises. A guiding principle is parsimony; we do not suggest adding complexity that is unsupported empirically.

We revised the energetics-based model (Biggins and others, 1993) to allow an effect of territoriality that is initiated at densities of 18 prairie dogs per hectare, gradually increases in intensity, and reaches an asymptote of 0.04 ferret families per hectare at a prairie dog density of 42/ha (fig. 2). Because a black-footed ferret family includes one female, we are discussing female ferret density. A quadratic equation ($Y = a + bX + cX^2$) adequately approximates the proposed curvilinear relationship within the range 18–42 prairie dogs per hectare, where: Y = predicted density of female ferrets, X = density of prairie dogs, a = -0.00456329, b = 0.00193283, and c = -0.00002083. If there are <18 prairie dogs per hectare, the equation for the straight line segment of the graph remains $Y = 0.00131062X$, a slope determined by the existing energetically based estimates and a linear relationship between ferret density and prairie dog density. Although white-tailed prairie dogs occasionally have been found at densities >20/ha, the graph suggests (correctly, we believe) that density of female ferrets seldom will be limited by territoriality on white-tailed prairie dog habitat. In contrast, we believe that territorial behavior of female ferrets will commonly influence their spacing on most black-tailed prairie dog (*Cynomys ludovicianus*) habitat. Under our proposed relationship, that influence will increase until female ferrets reach densities of about 1 ferret per 25 ha of habitat (the maximum density of 0.04 ferrets per hectare). We predict that prairie dog densities above 42/ha will not result in increased densities of territorial female ferrets, but these higher densities of prairie dogs may affect other population attributes such as ferret survival and productivity.

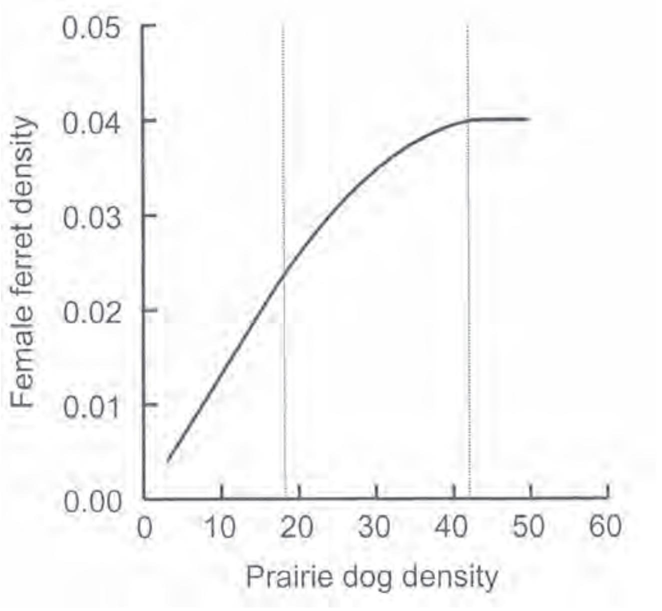

Figure 2. Hypothetical relationship between densities of prairie dogs (*Cynomys* spp.) and densities of female black-footed ferrets (*Mustela nigripes*) (individuals/ha), allowing territoriality to modify the linear relationship predicted by the energetics-based equation ($Y = X/763$) of Biggins and others (1993) at prairie dog densities >18/ha but defining an upper limit of 0.04 ferrets/ha. At intermediate prairie dog densities (18–42/ha), the increasing influence of territoriality is approximated by the quadratic equation $Y = a + bX + cX^2$, where Y = density of ferrets, X = density of prairie dogs, a = -0.00456329, b = 0.00193283, and c = -0.00002083.

Habitat-induced Isolation

"Islands" or "peninsulas" of habitat with high densities of prairie dogs may support more ferret families than would large blocks of uniform habitat because some configurations of habitat can reduce among-female interaction. An "island" arrangement with a colony small enough to support just one female and her litter (figs. 3 and 4) seems likely to eliminate any potential for limiting effects of territoriality. A "peninsula" configuration removes that effect on two sides, but territorial spacing comes into play for end-to-end territories along linear habitat. The example of 20 ha of prairie dog colony needed to support a female and her litter (fig. 3) is somewhat conservative. Five of the nine ferret litters reported by Hillman and others (1979) in Mellette County, S. Dak., were raised on colonies <16 ha in area (one was 10 ha). A female ferret raised two kits on a 5-ha colony in Montana (fig. 4); however, it seems doubtful that the Montana female could have accomplished that feat without seriously depleting the prairie dog population, and her small litter suggests that conditions may have been suboptimal. At Meeteetse, Wyo., the smallest colonies that supported females with litters were about 50 ha, but white-tailed prairie dogs at Meeteetse occurred at much lower densities (about 7.7/ha, calculated from the visual count density of Clark and others (1985) divided by the sightability adjustment of 0.495 of Biggins and others (1993)) than did the black-tailed prairie dogs discussed above (Hillman and Linder, 1973). We accommodate the most extreme of these influences of colony sizes and shapes into the evaluation procedure with a provision that removes the effect of territoriality if a colony is sufficiently small and isolated to support just a single female. To facilitate evaluation of prairie dog complexes as habitat for black-footed ferrets, a spreadsheet with appropriate formulae is available from the authors.

Colonies as small as the minimum mapping unit (5 ha) suggested by Biggins and others (1993) may support a female and her litter. Usually, however, colonies <10 ha will not have sufficient numbers of prairie dogs to sustain both themselves and a ferret family. Depletion of prairie dogs can be expected on colonies <10 ha if they are occupied by a ferret family, and it seems unlikely that such small colonies will support ferret reproduction in consecutive years. Nevertheless, we propose allowing colonies as small as 5 ha to contribute to the family rating of a complex by using the direct linear equation (Biggins and others, 1993), without the influence of

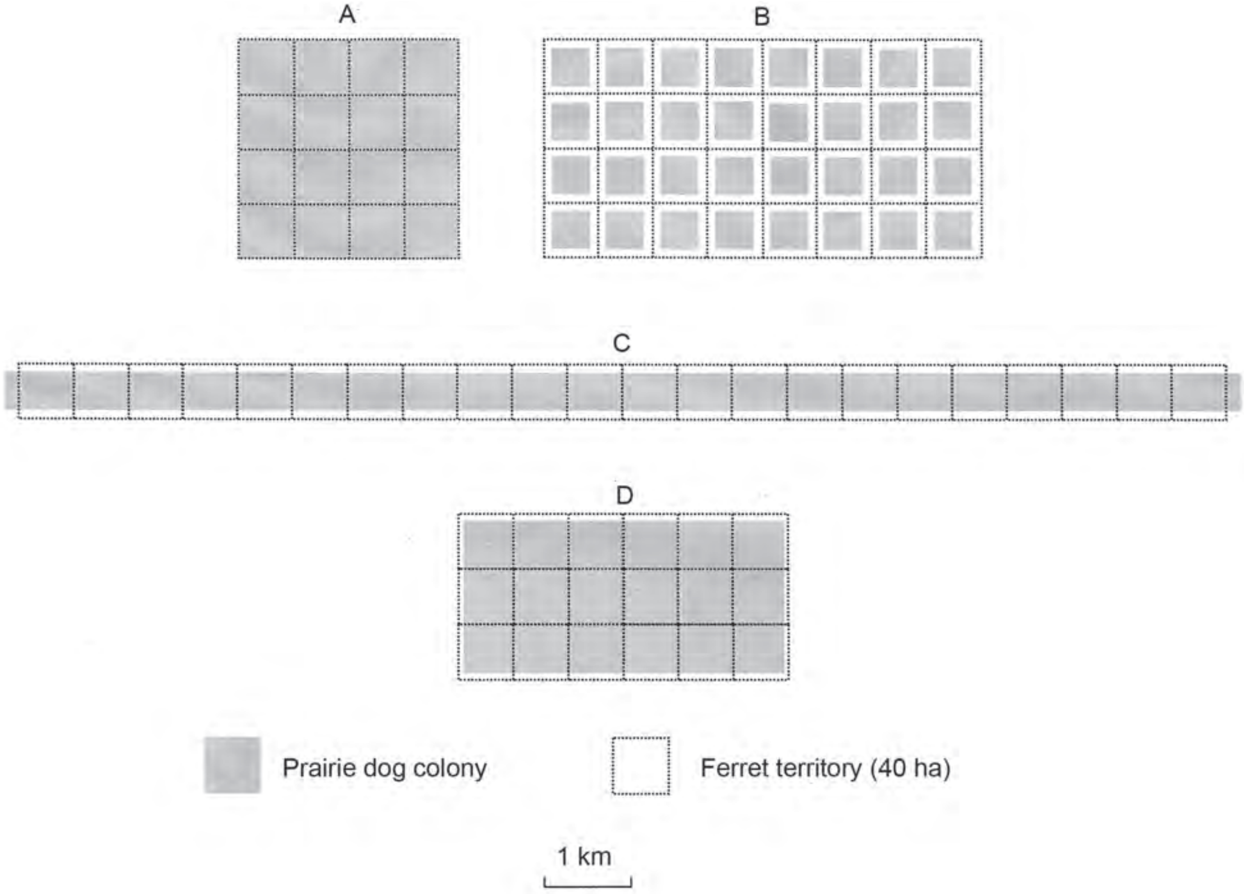

Figure 3. Comparison of female black-footed ferret (*Mustela nigripes*) numbers supported by hypothetical prairie dog (*Cynomys* spp.) complexes occupying 640 ha: (A) a complex with a single square colony (*n* = 16 ferrets); (B) a complex with 20-ha colonies at sufficient spacing to allow separate ferret territories (*n* = 32 ferrets); (C) a complex with a single linear colony (22 ferrets); and (D) a complex with a single rectangular colony (18 ferrets). These predictions are based on the following assumptions: (1) ferret territories are 40-ha squares, (2) a patch of prairie dog habitat occupying at least 20 ha is centered in the territory, and (3) a habitat patch of 20 ha has sufficient prairie dogs to sustain a ferret family while maintaining its prairie dog population.

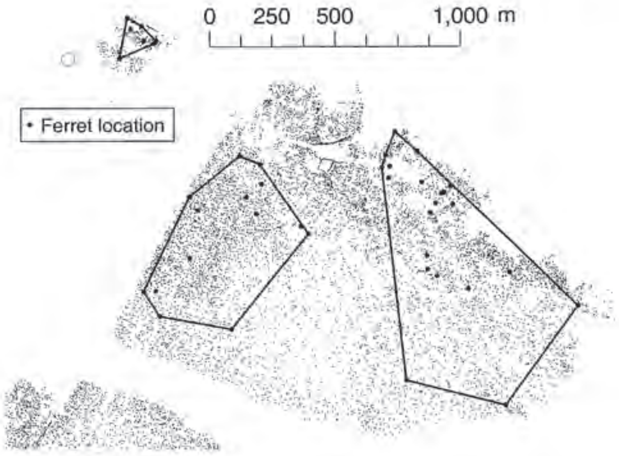

Figure 4. Activity areas (circumscribed by minimum convex polygons) for three female black-footed ferrets (*Mustela nigripes*) with litters. These females and their litters were repeatedly relocated during summer 1998 at UL Bend National Wildlife Refuge, Mont. Heterogeneity in dispersion of black-tailed prairie dog (*Cynomys ludovicianus*) burrows (small dots) is evident. The female ferret on the small colony is relatively insulated from repeated contact with other females. In this example, areas of dense prairie dog burrows do not form true "islands" of good habitat, but low densities of prairie dog burrows in the central portion of the larger colony may have influenced separation of ferret activity areas.

territoriality. If the rating using the linear equation is less than two female ferrets, then a single colony, regardless of size or prairie dog density, may be evaluated with the linear relationship (even if the result is a rating <1.0).

The concept of islands and peninsulas discussed above creates an image of prairie dog colonies within landscapes that have areas devoid of prairie dogs. Islands with high densities of prairie dogs, however, may also be situated within intervening habitat of low prairie dog density. Thus, the island effect may be operative within colonies that have heterogeneous densities of prairie dogs. The mosaic of prairie dog densities is reflected by nonuniform densities of prairie dog burrows. Heterogeneity in distribution of burrows may influence separation of activity areas of at least some female ferrets (fig. 4).

Another Look at Burrow Densities as Indicators of Prairie Dog Density

Biggins and others (1993) suggested that densities of active burrows were significantly correlated with densities of prairie dogs determined from visual counts. Severson and Plumb (1998, p. 864), however, failed to detect a relationship between densities of prairie dogs and their burrows, concluding that “burrow counts . . . should not be used to estimate or index prairie dog numbers.” This theme has a rather long history of debate extending to species other than prairie dogs, and a full discussion is outside the intended scope of this paper. Nevertheless, an overview of the topic and brief discussion of the specific criticism noted above are appropriate because working groups responsible for monitoring ferret reintroduction sites have made wide use of burrow sampling to calculate indices of habitat quality for ferrets. The need remains for a practical technique to monitor prairie dog status and trends over large scales of space (thousands of hectares) and time (decades). Decisions to use some form of capture-recapture method, visual counts, or burrow indices to estimate prairie dog abundance and density depend in part on objectives and available resources (Biggins and others, 2006). In addition, choice of method will be affected by precision and accuracy required.

Biggins and others (1993) provided only correlation coefficients for regression relationships between data from burrow transects and visual counts. To enhance comparisons with other data sets, more information is needed. Their data sets were generated from counts and transects on 30 white-tailed prairie dog plots and 39 black-tailed prairie dog plots. Using regression models with constants (Biggins and others [1993] reported regression through the origin), the relationships between densities of active burrows and density of prairie dogs as determined by visual counts were highly significant for both species (white-tailed prairie dogs, $F_{1,28} = 86.282$, $P < 0.001$, $R^2 = 0.755$; black-tailed prairie dogs, $F_{1,37} = 29.390$, $P < 0.001$, $R^2 = 0.443$). A comparison of the studies done by Severson and Plumb (1998) and Biggins and others (1993) reveals differences in several key features that collectively may affect the power to detect correlations (table 1). Collectively, the relative ranges of values and various levels of sampling intensity (e.g., plot size, number of plots, geographic coverage) should have given an advantage to the data sets of Biggins and others (1993). Intensity of transect sampling to estimate burrow density is as important as other features but was not reported by Severson and Plumb (1998).

Evidence of the utility of the burrow transect technique is also provided by data generated from its use. The overall collapse of the Meeteetse complex of white-tailed prairie dogs was documented by using densities of active burrows derived from strip transect sampling (fig. 5). It would be difficult to imagine that the downward trend during the 10-year study was an artifact of the sampling procedure, even without the corroborative evidence that exists from visual counts (D.

Table 1. Attributes of two studies on the relationship between densities of black-tailed prairie dogs (*Cynomys ludovicianus*) and densities of their active burrows.

	Severson and Plumb (1989)	**Biggins and others (1993)**
Number of States	1	3
Number of plots	24	39
Plot size (ha)	4	9
Area sampled (ha)	96	351
Burrow transects (km)	?	248
Lowest prairie dog density (no./ha)	8	0.8
Highest prairie dog density (no./ha)	46	54.2

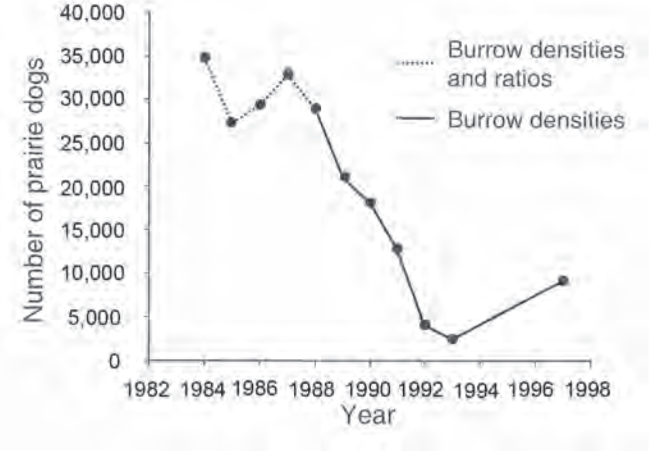

Figure 5. Estimates of white-tailed prairie dogs (*Cynomys leucurus*) on the Meeteetse, Wyo., complex, derived from estimates of active burrow density (Biggins and others, 1993). (Adapted from Biggins and Kosoy, 2001. Reprinted with permission of the *Journal of the Idaho Academy of Science*, Pocatello, Idaho.)

Biggins, unpub. data, 1988–93) that were repeated annually over most of that time period.

The purpose of the foregoing discussion is simply to provide evidence that burrow indices are a useful tool for indexing prairie dog abundance. This does not imply superiority of the technique compared to other tools; methods must be matched to objectives, size of area to be sampled, local conditions, and available funding.

Reemphasizing Percent of a Complex Occupied by Prairie Dog Colonies

Spatial relationships and shapes of prairie dog colonies were discussed above in the context of small islands and peninsulas of habitat with high prairie dog densities. Others (Forrest and others, 1985; Houston and others, 1986; Miller and others, 1988; Biggins and others, 1993) have discussed spatial arrangements of prairie dog colonies at larger scales, implying that some measure of colony arrangement or density within a complex is necessary to adequately evaluate habitat quality for black-footed ferrets. The 7-km limitation to intercolony spacing (Biggins and others, 1993) was a partial solution, but, without additional criteria, vast complexes that are thinly populated with prairie dog colonies may provide the same rating as complexes with more compact arrangements of colonies (fig. 6). There have been theoretical problems with measures of colony dispersion such as intercolony distances (Biggins and others, 1993), ultimately leading the ICC to adopt the conceptually simple tactic of using percent occupied (100 × sum of colony area/total area of complex) proposed by Miller and others (1988). During the first decade of ferret reintroductions, however, the spatial arrangement of prairie dog colonies within complexes largely has been ignored. Few participants have bothered to calculate the percent occupied attribute suggested as an overview of dispersion of colonies. By invoking the new procedure for defining subcomplexes of colonies spaced at 1.5 km or less, the consequences of this oversight are diminished (but not eliminated). It will be possible to examine how much of a complex consists of high-quality "core" subcomplexes. Subcomplexes should be rated separately from 7-km complexes; they should no longer be considered as having equal quality to complexes with the same cumulative area occupied by prairie dog colonies (fig. 6C versus 6A and 6B). Nevertheless, calculation of the proportion of complexes and subcomplexes occupied by prairie dog colonies will provide useful additional information (e.g., to distinguish between complexes such as A and B of fig. 6), and we continue to recommend that management teams at all reintroduction sites make these simple measurements. The technique will allow improved comparisons of complexes and subcomplexes among and within ferret reintroduction sites and may help characterize the potential for colony expansion.

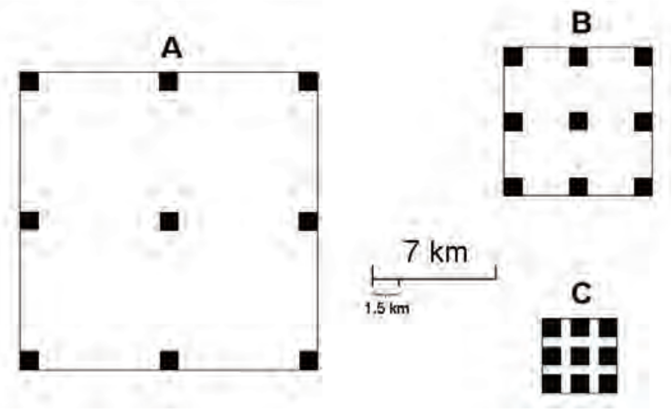

Figure 6. In these three hypothetical complexes, total area occupied by prairie dog (*Cynomys* spp.) colonies (shaded squares) is the same (1,000 ha), but the percentages of each complex occupied by colonies are 4%, 14%, and 57% for A, B, and C, respectively. Are the complexes of equal quality as habitat for black-footed ferrets (*Mustela nigripes*)? Arrangement C qualifies as a subcomplex because of intercolony spacing of <1.5 km.

Summary of the Procedure for Evaluating Ferret Habitat

The following steps for evaluating habitat for black-footed ferrets summarize the approach suggested by Biggins and others (1993) and the modifications presented herein.

1. Map the complex of prairie dog colonies.
2. Circumscribe the complex by using the 7-km criterion.
3. Circumscribe high-quality subcomplexes by using the 1.5-km criterion.
4. Estimate areas of complex, subcomplexes, and colonies with geographic information system (GIS) software if maps are digital. Use polar planimeter or other methods (e.g., dot grid) to estimate areas if only hard copies of maps are available.
5. Calculate percent of complex and subcomplexes occupied by prairie dog colonies.
6. Estimate prairie dog densities on colonies by using burrow density transects or visual counts.
7. Enter density and area estimates for each colony into separate spreadsheets for the overall complex and all subcomplexes.
8. Calculate ferret family ratings by using modified formulae (example spreadsheets with formulae are available from the authors).

Assumptions and Unresolved Questions

We believe that the suggested modifications discussed above will improve the existing model but reiterate that any model is only an approximation of reality (Biggins and others, 1993). Reflection on the basic assumptions involved in this exercise serves as a reminder of its inexact nature. Assumptions include (1) the average prairie dog weighs 760 g, (2) a ferret wastes 20 percent of each prairie dog it kills, (3) the several steps involved in estimating caloric demands of ferrets are correct, (4) losses of prairie dogs to other causes are 250 percent of losses caused by ferret predation, (5) the intrinsic rate of growth for prairie dog populations (λ) is 1.0, and (6) prairie dog populations remain stable. A sobering fact is that some of these attributes vary widely (e.g., numbers 4 and 5) and are in need of further study. The earlier model implicitly assumes that all prairie dogs, regardless of sex or age, are equally available as prey. If female ferrets selectively prey upon juvenile prairie dogs, their own productivity may be more closely correlated with prairie dog productivity than with prairie dog density. This possibility leads to questions about links between forage production, prairie dog production, and ferret production and highlights the potential importance of local and annual variation in precipitation.

A better understanding of prairie dog torpor (Lehmer and Biggins, 2005), burrow-plugging behavior, and energetics of ferret digging behavior could also improve the quality of these models. Is the digging involved in excavating hibernating prey more energetically costly than hunting of nonhibernating prey (Harrington and others, 2003)? What is the balance in tradeoffs between energetic costs of accessing prey and risk of injury in killing prey when comparing hibernating and nonhibernating prairie dogs? Does the presumably lower risk involved in killing hibernating prey allow use of larger prairie dogs that might not otherwise be available?

Territoriality in ferrets also remains poorly understood. Key questions include the following: (1) At what densities of prey does control of minimum space take precedence over control of prey resources? Can our proposed curve be further refined? (2) Does nepotism affect territory size and overlap (i.e., are females more tolerant of their female offspring than of less closely related females)? (3) How do shapes and arrangements of high-quality patches within and among colonies affect territorial behavior?

Some related topics would be appropriate for additional investigation. The earlier attempt to define minimum habitat attributes necessary to sustain female ferret reproduction (Biggins and others, 1993) may be questioned. Further study of female ferret behavior on white-tailed prairie dog or Gunnison's prairie dog (*Cynomys gunnisoni*) colonies, where prey densities are low, would help establish the lower limits. Preliminary data suggest a positive correlation between productivity of female ferrets and density of burrows in the habitat they occupy (D. Biggins, M. Matchett, and T. Livieri, unpub. data, 1997–2000), a relationship that also suggests further research on habitats with low prey densities. Territorial behavior of male ferrets has been ignored but may be an important factor in extinction risk for small populations (Conservation Breeding Specialist Group, 2004). Increasing numbers of black-footed ferrets in reintroduced populations are providing more opportunity to investigate these and other important aspects of ferret ecology.

Section V. Reestablishing Populations

Reintroduction of black-footed ferrets was a primary focus of attention during the decade of the 1990s. This phase of recovery was envisioned in the 1988 recovery plan to encompass experiments with rearing of ferrets, development of monitoring techniques, testing of release methods, and further investigations of black-footed ferret ecology. Experiments with rearing and release of ferrets have been conducted. Improved rearing methods and prerelease conditioning have dramatically enhanced postrelease survival of ferrets, and a new captive breeding center was designed to accommodate those methods. Other data from many ferret releases have been evaluated to produce the papers of this section.

Monitoring Black-footed Ferrets During Reestablishment of Free-ranging Populations: Discussion of Alternative Methods and Recommended Minimum Standards

By Dean E. Biggins,[1] Jerry L. Godbey,[1] Marc R. Matchett,[2] Louis R. Hanebury,[3] Travis M. Livieri,[4] and Paul E. Marinari[5]

Abstract

Although the monitoring of black-footed ferret (*Mustela nigripes*) populations following reintroductions has not been haphazard, several ferret recovery groups since 1994 have recommended development of uniform standards prescribing minimum methods, intensities, and frequencies of monitoring that would provide data on population size, mortality rates, and recruitment. Such standards would promote comparability of data among sites, document expectations for those who will attempt to establish new populations, and allow the U.S. Fish and Wildlife Service and other responsible groups to better assess progress made toward achieving recovery objectives. Our recommendations are based on methods that have been successfully used to monitor natural and reintroduced populations of ferrets and are an attempt to balance needs and costs. We suggest a combination of marking ferrets with passive integrated transponder (PIT) tags and annual spotlight searches coupled with automated transponder readers to individually identify survivors. Unmarked ferrets should be captured and implanted with PIT tags whenever possible. These and other methods are detailed. Circumstances that may dictate other methods or more intensive monitoring (e.g., high rates of loss or low recruitment) also are discussed.

Introduction

The need to prescribe standards for monitoring black-footed ferrets (*Mustela nigripes*) at reintroduction sites has become apparent to the U.S. Fish and Wildlife Service (FWS) and members of the Black-footed Ferret Interstate Coordinating Committee (ICC), who discussed formulating standards at the ICC annual meetings of 1994 and 1995. That need was reaffirmed as an action item in an American Zoo and Aquarium Association program review (Hutchins and others, 1996) and at the Black-footed Ferret Conservation Subcommittee (of the Black-footed Ferret Recovery Implementation Team) meeting of 2001. Standards are needed in order to (1) accurately assess progress toward recovery goals, (2) clearly define monitoring expectations for future sites for black-footed ferret reintroduction, (3) provide guidance regarding methods and associated limitations, (4) assure FWS that participants provide consistent feedback on progress, and (5) make limited data comparable for broad-scale interpretations.

The need for standards does not imply that monitoring is presently haphazard. Indeed, several groups releasing black-footed ferrets have used similar strategies, most commonly spotlighting, to evaluate ferret status and trends; however, standardizing would increase the opportunity for comparisons among sites, years, and other variables of interest. Our suggestions are an attempt to balance needs and cost. Our goal was to prescribe methods that maximize applicability of the most basic data but would not preclude any group from participation because of cost. Reviews of monitoring efforts during the early years of ferret reintroductions in Wyoming, Montana, South Dakota, Arizona, Utah, Colorado, and Mexico revealed strengths and weaknesses that influenced our recommendations. This prescription defines minimum levels of monitoring, but we encourage all working groups to consider using more intensive monitoring efforts, when applicable, to help address questions of importance to recovery goals.

We are not suggesting procedures for so-called clearances (U.S. Fish and Wildlife Service, 1988) related to section 7 of the Endangered Species Act, although some of the techniques we discuss are useful for those purposes. We do not exhaustively analyze or describe methods beyond the minimum

prescription (e.g., radio telemetry) but provide references for more information on those topics. We describe monitoring of black-footed ferrets only; monitoring of prairie dog populations, associated species, and diseases at reintroduction sites is also important, but such topics are beyond the scope of this paper.

Objectives

To monitor is to watch, observe, or check, especially for a real purpose (*Webster's New Collegiate Dictionary*). Monitoring is needed to accomplish the following objectives:

- assess progress toward site-specific population establishment and make attendant decisions related to the need to continue to release captive-bred animals and numbers that should be released,
- detect serious problems or catastrophic population declines (e.g., due to diseases) that might be remediated,
- assess recovery at the national level, and
- test hypotheses regarding methods involved in establishing self-sustaining ferret populations (e.g., rearing, release, translocation, disease prevention, ferret searches, predation reduction).

Specifically, monitoring may provide data to (1) estimate population size, composition, and rates of natality and mortality; (2) assess genetic representation within a population; (3) identify causes of mortality; (4) document spatial distribution of ferrets including dispersal and habitat use; and (5) assess condition of ferrets, exposure to diseases, and parasite loads.

Types of Data: Balancing Needs and Costs

Useful minimum monitoring levels must produce information that identifies whether or not there are serious problems and allows assessment of progress toward local and national recovery goals (the first three objectives listed above). If losses of ferrets are low during initial releases, and if later populations appear to be self-sustaining, then monitoring can be maintained at these minimum levels. If problems are evident (e.g., excessive losses of ferrets), then we suggest increased levels of monitoring to identify their causes. The alternatives are site abandonment or sustained augmentation of ferrets. Abandonment does not contribute to our understanding and may result in repeated mistakes. Sustained augmentation seems inefficient but may, in the end, be needed at some sites.

The fourth listed objective of monitoring relates to experimentation and hypothesis testing to better understand the ecology of ferrets and improve reintroduction strategies, thereby enhancing the prospect for successful species recovery. This objective may necessitate monitoring that is different and sometimes more intensive than the minimum levels prescribed below. This learning objective is sufficiently important to programmatic decisions that it may at times take precedence over other objectives. Needs vary by site and year; further discussion of this objective is beyond the scope of this paper.

Minimum data needed to accomplish the first three objectives are estimates of population size, survival rates, and annual recruitment. A critical review of the last four decades of black-footed ferret monitoring, however, reveals that there never have been estimates of these attributes that were free of known biases. Recently, we have qualified these estimates as “minimums,” recognizing that not all ferrets will be found (Biggins and others, 1998). Moreover, “survival” rates should really be termed “retention” rates, where failure to retain ferrets at a reintroduction site can be due to emigration or mortality. Retention rates are likely biased downward because of undetected ferrets, but actual survival rates could be higher than retention rates if dispersal away from the reintroduction sites occurred without concurrent mortality. Population size, survival, recruitment, and associated variances can be estimated with closed form models or iterative numerical optimization if unbiased surveys are repeated over short time spans (Otis and others, 1978; White and others, 1982), and even more analytical tools are available if those multiple surveys done in short spans are replicated again over longer spans (robust designs: Kendall and others, 1995; Hines and others, 2003; program MARK: White and Burnham, 1999). The increased effort in repeated surveys is obvious, but avoiding bias caused by observer familiarity gained during previous surveys calls for additional constraints, problematic logistics, and even greater costs. Thus, we believe that the effort required could not be sustained over multiple reintroduction sites and years; the 24-year history of rather intensive monitoring of black-footed ferrets provides ample evidence regarding how much can be accomplished with available resources. Realistically, the tactics that have been used over the past 10 years are likely to remain the ones used to monitor black-footed ferret populations in the future, and the measures of population size, survival, and recruitment obtained by those monitoring methods (described below) will have to serve as indices to population attributes.

Although those indices (e.g., population size) are biased, they are nearly always based on complete coverage of respective reintroduction sites during spotlight surveys. Thus, issues of spatial sampling are not relevant. Although coverage may be complete, the counts are not a census because all ferrets are not found. We do not regard this bias as a fatal flaw, in part because it is unlikely to be large and in part because the counts can be adjusted for effort, providing indices that are particularly useful in a comparative sense (e.g., comparisons among groups and years within sites). Diminishing cumulative detections of unique ferrets over several days of spotlight searches (discussed below) provide reassuring evidence that large numbers of ferrets usually do not remain undetected during spotlight surveys. The standardization of search methods suggested below also will enhance comparability of data sets.

Data Collection Methods

Relatively few techniques have proven effective to “watch, observe, and check” black-footed ferrets; each method has its advantages, disadvantages, limitations, and risks. The methods currently used are snow tracking, spotlighting, capture-mark-recapture, and radio telemetry, but each can be utilized at varying levels of intensity and can be coupled with other strategies to increase the quality and quantity of data. Indeed, use of multiple methods allows cross-checking and verification of data.

Snow Tracking

Snow tracking involves searching from the ground or aircraft to locate tracks and other sign (especially diggings) of black-footed ferrets. Individual ferrets can sometimes be identified based on geographic location of tracks and origin and terminus points. Counts can be cumulative, giving an estimate of ferret numbers, provided that snow conditions remain optimal for at least several days. The strategy involves searching along ground transects (Richardson and others, 1987) or aerial flight lines (Biggins and Engeman, 1986; Miller and Biggins, 1988) until tracks or diggings are encountered. Track sets then are individually followed from origin to terminus to determine individuality and gather accessory information on movement pattern (use of space, but only crudely related to time) and to opportunistically collect scat for diet information. Broad-scale searches for tracks have revealed the presence of ferrets on prairie dog colonies that would not otherwise have been monitored. Absence of tracks, however, does not prove absence of ferrets because ferrets may remain inactive for many days following a snowstorm.

Snow tracking is least likely to adversely impact ferrets, requires little specialized equipment, and is relatively inexpensive. The principal disadvantage is weather dependency; although snow is common in the northern and western portion of the ferret’s original range, good tracking conditions occur only sporadically. Best results are attained when snow cover is continuous and undisturbed for several days. Warm sunny spells can cause patchiness, and winds can quickly erase evidence. Prairie dog (*Cynomys* spp.) tracks cause confusion during searches from the air and ground and may obliterate ferret tracks; however, white-tailed prairie dogs (*C. leucurus*) and Gunnison’s prairie dogs (*C. gunnisoni*) routinely hibernate, and black-tailed prairie dogs (*C. ludovicianus*) also may enter torpor (Lehmer and others, 2001), allowing effective midwinter ferret searches during prolonged spells of calm, cold weather following accumulations of snow. A team of searchers must respond immediately when favorable conditions develop. Each site should have a snow-tracking plan targeting priority areas for searches so that implementation can be rapid and efficient. Identification of mustelid tracks is not always straightforward; long-tailed weasel (*Mustela frenata*) tracks cause potential confusion (Miller and Biggins, 1988). Individual identities of ferrets can be ascertained if they have been marked with passive integrated transponder (PIT) tags (see subsection on Capture, Handling, and Marking). If ferrets are not individually identified, conservative time and space separation criteria should be used (see subsection on Minimum Level of Monitoring) to determine the minimum number of different ferrets present because ferrets can move long distances each night and because several ferrets can reside in close proximity.

Spotlighting

Spotlighting has been the universal technique for finding black-footed ferrets (Campbell and others, 1985). Prairie dog colonies are scanned at night with high-intensity spotlights by individuals on foot or in vehicles (e.g., all-terrain vehicles or trucks). Recently, most spotlighting has been conducted by using continuous illumination while the observer moves slowly (10 km/h), but earlier workers, searching on relatively small prairie dog colonies, preferred a systematic schedule of intermittent illumination from a fixed location (Henderson and others, 1969; Fortenbery, 1972). Standardization to the extent possible is very important because variation in the manner of implementation can lead to erratic results, but standardization must be balanced with site-specific needs.

Compared to snow tracking, spotlighting gives much more accurate temporal data to accompany spatial data. The eyes of ferrets reflect an emerald green shine, but other animals, such as badgers (*Taxidea taxus*), coyotes (*Canis latrans*), weasels (*Mustela* spp.), deer (*Odocoileus* spp.), and pronghorns (*Antilocapra americana*), can cause confusion. Interorbital distance, distance from ground, and behaviors help distinguish ferrets from some other mammals, but distances can be deceiving at night, and experience is necessary for reliable and efficient identification. Coyotes tend to briefly look at the spotlight, run a short distance, stop, and then look at the spotlight again. Weasels dart about much more quickly than ferrets and have a more subdued eyeshine. Swift foxes (*Vulpes velox*) run with a rigid gait, so the eyeshine does not undulate, then may stop and briefly lay close to the ground. When ferrets are moving, their eyeshine tends to bounce because of their bounding gait. Deer and pronghorns have much larger eyes and tend to be bedded down at night in groups; their eyeshine rises when they stand up.

Reported detection rates range from 1.4–102.6 hours per black-footed ferret sighting and up to nearly 264 hours per unique ferret located (table 1) for surveys of reintroduced and wild populations. Sighting rates are influenced by ferret density, but topography, vegetation, and varying behaviors of the animals (e.g., because of weather, season, origin of stock, rearing method) may also contribute to variation in sightability

Table 1. Examples of search efforts expended for locating black-footed ferrets (*Mustela nigripes*) with spotlights.

Location	Time	Source	Hours	Number of hours/ ferret sighting	Number of hours/unique ferret sighting

(Marinari, 1992). The probability of detecting an individual free-ranging ferret with spotlights has not been estimated for any set of conditions. Cumulative counts over time, however, have been plotted and may generically illustrate probability of detection during short time spans, assuming no mortality occurs. Data from the Meeteetse, Wyo., population of ferrets on white-tailed prairie dog habitat suggest that about 82 percent of the cumulative total number of ferrets had been counted after four nights of spotlight searches (Forrest and others, 1988). Similar data from spotlighting in 17 black-tailed prairie dog colonies in the Conata Basin of South Dakota (T. Livieri, unpub. data, 2002) resulted in a steeper curve, with 92 percent of the cumulative total counted after three nights and 98.5 percent counted after four nights (fig. 1). For the South Dakota data set, the cumulative proportion of ferrets counted also increased as a function of cumulative time spent spotlighting adjusted by area covered during the search (fig. 2). Although most ferrets appear to be found during diligent searches, individuals can be elusive. In Utah, a female remained undetected for 24 months (three surveys) (B. Zwetzig, oral commun., 2004); in Arizona, two females were not located for 27 months (Hoss and others, 2004); and an adult male in South Dakota was first relocated 40 months after release (W. Perry, oral commun., 1998).

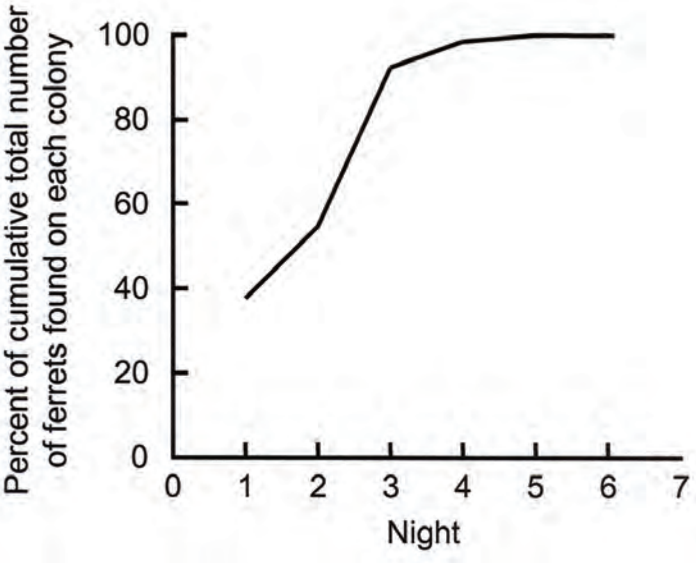

Figure 1. Black-footed ferrets (*Mustela nigripes*) encountered per night during spotlight searches on 17 black-tailed prairie dog (*Cynomys ludovicianus*) colonies, September 16-22, 2002, in Conata Basin, S. Dak.

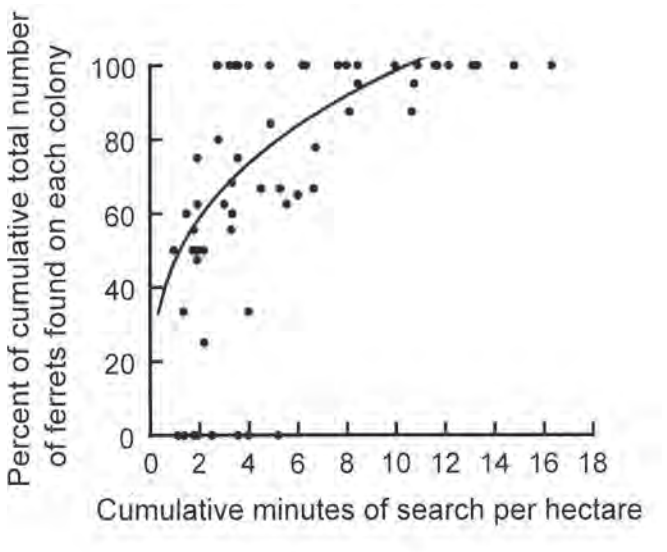

Figure 2. Black-footed ferrets (*Mustela nigripes*) encountered per minute per hectare during spotlight searches on 17 black-tailed prairie dog (*Cynomys ludovicianus*) colonies, September 16-22, 2002, in Conata Basin, S. Dak. An exponential curve was fitted to data.

Table 2. Percent of the cumulative total number of black-footed ferrets (*Mustela nigripes*) counted during 1999–2002 at Conata Basin, S. Dak.

	Cumulative counts				
	1999	**2000**	**2001**	**2002**	**Mean**
			Males		
July–August	71.4	70.0	85.2	65.4	73.0
September	92.9	76.7	92.6	96.2	89.6
October	92.9	93.3	100.0	100.0	96.6
November	100.0	96.7	100.0	100.0	99.2
December–on	100.0	100.0	100.0	100.0	100.0
			Females		
July–August	93.9	92.9	88.3	94.1	92.3
September	100.0	100.0	95.0	100.0	98.8
October	100.0	100.0	100.0	100.0	100.0
November	100.0	100.0	100.0	100.0	100.0
December–on	100.0	100.0	100.0	100.0	100.0

Cumulative total spotlight counts of ferrets continue to increase over time spans of months, but in these longer spans it is not reasonable to assume that the estimates are unaffected by losses of animals. For a 4-year data set from South Dakota (T. Livieri, unpub. data, 1999–2002; data from those colonies that were repeatedly searched each month), monthly detection rates for males appeared to be lower than rates for females (table 2). Assuming a constant monthly survival rate of 0.9763 (annual survival of 75 percent), the increasing cumulative monthly counts in table 2 can be approximated by (constant) monthly spotlight detection rates of 0.722 for males and 0.918 for females. These estimates need refinement but seem to reflect differences in ability to detect adult males and adult females with spotlight searches.

Spotlighting can alter behaviors of black-footed ferrets. Responses to the lights seem to vary among individual ferrets. Some ferrets may avoid the light by decreasing aboveground activity, and others may attempt to escape through increased movements (Campbell and others, 1985). Spotlights emitting white light probably should not be used for prolonged observations of a ferret (Campbell and others, 1985). More equipment (e.g., spotlights, backpack units, batteries) is needed for spotlighting than for snow tracking. Similar to snow tracking, located ferrets can be identified with remote transponder readers or through capture.

Capture, Handling, and Marking

Whether ferrets are located by spotlighting or snow tracking, identification of each individual may enable (1) cumulative minimum counts of animals while positively avoiding double counting, (2) an overview of dispersal movements, (3) tests of hypotheses regarding comparisons between treatments (e.g., rearing conditions, sex, site, habitat use, release method; Biggins and others, 1998), and (4) assessment of likely matrilineal relationships within populations (Biggins and Godbey, 2003). With some monitoring designs, marking also may allow (1) use of mark-recapture methods for population estimation (Otis and others, 1978; White and others, 1982; White and Burnham, 1999; Rivest and Daigle, 2004), (2) use of survival estimators (Lebreton and others, 1992), and (3) estimation of age-specific mortality rates.

Successful methods for marking ferrets are passive integrated transponder (PIT) implants (Fagerstone and Johns, 1987) and ear tattoos (Fagerstone and others, 1985). Tattoos are usually identifiable only on ferrets that are in hand and sometimes become illegible or disappear entirely. Less commonly, transponders have ceased functioning or have been lost from the ferrets. Passive integrated transponder tags are relatively inexpensive and easy to install and have become the preferred technique for marking ferrets. Two transponders should be implanted, one on the posterior part of the head and the second dorsally between the hips. After a ferret has been located by spotlighting or snow tracking, its transponders can be identified with an automated reader that is left at the occupied burrow (Stoneberg, 1996) (fig. 3), or the ferret can be captured and identified with a hand-held reader.

If an attempt at automated transponder reading fails, capture can be used as a backup. Capture involves additional stress on animals (Thorne and others, 1985) but provides an

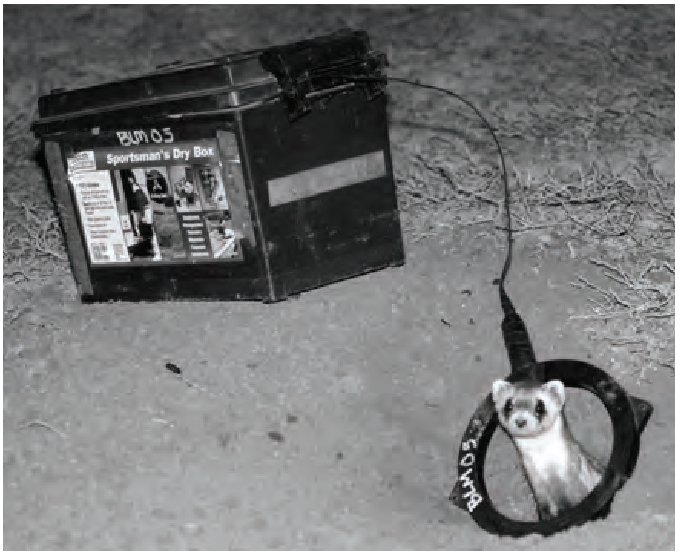

Figure 3. Automated passive integrated transponder readers in waterproof boxes may be left at burrows occupied by black-footed ferrets (*Mustela nigripes*). Transponder numbers will be recorded as the ferret passes near (or through) the loop antenna placed to encircle the burrow entrance.

opportunity to assess condition and take samples of blood, parasites, etc. These samples could prove invaluable in disease evaluations and for genetic studies. Traps (see fig. A1 in appendix) must be in good working order. It is exasperating to find a malfunctioning trap at the end of an extended attempt to capture an animal. If a burrow system is thought to have multiple openings, openings lacking traps may be plugged with rocks, wood, or plastic cups (44 oz). When trapping is finished, all traps must be retrieved, and all burrows must be unplugged.

Dye marking captured ferrets can prevent double counting during a survey and helps identify ferrets already captured during a trapping session. Dye can be applied to captured animals without use of anesthetics. Effective dyes include Nyanzol D (Hoogland, 1995) and hair dyes. Dyes, however, are temporary compared to transponders, lasting at best until the next molt; PIT tags should be used whenever possible, whether or not fur is dyed.

Anesthesia is necessary for many of the procedures mentioned above. Anesthetics used in the field on black-footed ferrets have included ketamine, a ketamine-medetomidine mixture (reversed with atipamezole) (Kreeger and others, 1998), telazol, and isoflurane. Gas anesthesia (including isoflurane) requires a relatively bulky and complicated apparatus, including an induction chamber, vaporizer, mask, oxygen bottle, and connecting tubes. Isoflurane, however, allows a highly controllable level of anesthesia and maintenance of much higher blood oxygen concentrations (Gaynor and others, 1997).

Field technicians who need to capture and handle black-footed ferrets must complete a certification course. Presence of a veterinarian is beneficial when using anesthetics and handling ferrets. Ferrets should not be released until fully recovered from anesthesia, which may take hours with some injectable anesthetics.

Radio Telemetry

Radio telemetry has been used on black-footed ferrets since 1981 (Biggins and others, 1985, 1986). Telemetry has distinct advantages; animals are individually identifiable from remote locations with minimal human disturbance, behaviors can be monitored remotely (e.g., movements, home ranges, activity cycles, dispersal), fates can be identified, additional methods of survival analysis are available (Heisey and Fuller, 1985; Pollock and others, 1989), causes of mortality can be identified, and habitat use can be objectively assessed (White and Garrott, 1990). Disadvantages include the expense and impact of placing transmitter packages on or in the animals. Ferrets are assumed to be influenced by a transmitter, whether external or implanted; the effect can vary from trivial to devastating. Discussions about whether or not to use radio telemetry should focus on the degree of suspected impact weighed against potential gains in knowledge. Neck abrasions have been caused by collars, and premature collar loss has been common. The currently recommended collar is made of wool and degrades within several weeks to months (Biggins, Godbey, Miller, and Hanebury, this volume).

Compared to spotlighting and snow tracking, radio telemetry on black-footed ferrets is expensive and relatively difficult to master. Use of radio triangulation during ferret reintroductions has concentrated on intensive but short-term (30–60 days postrelease) data collection to compare behaviors of animals and document their fates (Biggins and others, 1999: Biggins, Godbey, Livieri, and others, this volume). Less labor-intensive, automated signal detection was used in releases of ferrets in South Dakota and Montana with emphasis on determining fates of ferrets, but interpretation of data was problematic. Because of the large commitment of time and funds and the possibility of adverse impacts on ferrets carrying transmitters, we regard radio telemetry as a specialized tool that should not be considered for routine monitoring of black-footed ferrets (Biggins, Godbey, Miller, and Hanebury, this volume).

Alternative Techniques

Other techniques that have been used in attempts to locate ferrets include scent dogs (Reindl, 2004); scent attractants coupled with remote cameras or transponder readers; implantable radio transmitters; long-range transponders; night vision equipment, such as light amplifiers and infrared detectors; and track plates. To date, these techniques have not proved widely applicable under field conditions, but they may become more useful in the future.

Recommended Standards

Minimum Level of Monitoring

Under the present circumstances and state of technology, we recommend marking all ferrets, including as many wild-born individuals as possible, with two transponder chips; spotlighting to locate black-footed ferrets; and identifying all ferrets located by using combinations of remote transponder readers and capture. Dye marking in addition to PIT tagging can allow the searchers to bypass ferrets, avoiding the need to set a reader or capture the animals to find out if they have already been PIT tagged. Failure to read the PIT tag each time a ferret is located, however, may preclude more rigorous assessments of population attributes and ferret movements. Exactly how these tools are deployed depends on the phase of reintroduction and the objectives for monitoring.

For sites where ferrets are released in fall, we recommend a minimum of two spotlighting periods, the first beginning 30 days after the final release (if there were several, closely spaced, sequential releases) and the second, postreproductive survey beginning in August of the following year. An existing ferret population that has not received additional releases of ferrets during the previous 12 months may be monitored with an August survey only. A prebreeding survey in March–April is highly desirable (for both recently released and established populations) but is not considered a requirement. If possible, ferret searches should be conducted during bright moonlight. Preliminary analyses for Siberian polecats (*M. eversmannii*) and black-footed ferrets suggest that radio-tagged individuals of both species were more active during bright nights (full moon) than during dark nights (new moon); when the moon was partially illuminated, they were more active during the part of the night when moonlight was present than when it was absent (Biggins, 2000).

Clark and others (1984) suggested methods for locating ferrets, and the FWS later recommended criteria for black-footed ferret surveys to clear prairie dog towns for development activities, application of toxicants, or other actions that might be detrimental to an existing population of black-footed ferrets (U.S. Fish and Wildlife Service, 1988). Because the guidelines were developed from techniques used at Meeteetse to monitor a wild population, some aspects are applicable to the standards proposed here for monitoring released ferrets. The basic recommendations of the survey guidelines are reiterated below, and each of these is followed by suggested modifications (if any) applicable to the minimum standards for monitoring reintroduced ferret populations.

1. When monitoring existing populations, surveys should be conducted between August 1 and September 30. This is the period when young ferrets have become sufficiently active above ground that they can be captured for marking, and it is normally prior to dispersal so that litters are usually separately identifiable. Adult males seem to be less detectable than adult females during this period (table 2).

2. Prairie dog towns should be continuously surveyed between dusk and dawn on each of three to five consecutive nights to ensure systematic coverage and increased opportunity to discover black-footed ferrets. A ferret can stay inactive for days (Biggins and others, 1986; Richardson and others, 1987), presumably depending on weather and its food supply. We suggest adding more nights (if necessary) until no (or few) new ferrets are found. If scheduling dictates that spotlighting cannot be continuous from dusk until dawn, then gaps in coverage should be rotated among nights so that no time period is neglected.

3. Detection depends on the ferret being above ground and facing the observer at the time the spotlight is directed toward it. Pass the spotlight across the landscape, and follow with a sweep back across the same path. A ferret looking away from the light during the first pass may become curious and turn toward the light on the second pass. Large prairie dog towns should be divided into tracts, and each tract should be systematically and repeatedly searched. Each searcher should concentrate on an area that ensures at least one pass every 30–60 minutes. Rough terrain, dense vegetation, and lack of road access may dictate small tracts to result in effective coverage. On occasion, the objective may be only to document presence or absence of ferrets on colonies, in which case tracts could be large (up to 800 ha). The area should be as small as practical to increase the opportunity for detection. In some cases backpack spotlighting may be necessary (e.g., if vehicle access is impossible or legally restricted). If searches are done on foot, then each person should concentrate on about 130 ha or less. Boundaries of tracts should be well marked to keep searchers oriented at night.

4. Observations on each prairie dog town or tract searched should begin at a different geographic point on each successive night to maximize the chance of intercepting a black-footed ferret during its nighttime activities, the patterns of which tend to be somewhat animal specific and repetitive. Even within a night, searchers should consider varying their search patterns while ensuring even coverage (e.g., alternate traveling north-south and east-west).

5. Previous guidelines suggested that survey crews consist of one vehicle and two observers equipped with two spotlights of 200,000–300,000 candle power. Teams searching for ferrets in areas with known populations have used a wider variety of equipment and organizational strategies. Single searchers on foot, in trucks, and with all-terrain vehicles (ATVs) have been effective, and other types of spotlight equipment also have been used. Because relative efficiency of various strategies is somewhat site dependent, we propose no limits. Use equipment that is suitable for the weather, terrain, and personnel.

Additional specifications include the following:

1. It is better to search each site entirely within a short time span by using a large number of searchers than to use few people over a long time span. The long-span, low-intensity method leads to problems in specifying the time interval for which the estimate is relevant (e.g., for estimating survival) and increases potential for confusion in counting individuals that are not recaptured or otherwise identified (e.g., double counting or missing ferrets that moved).

2. Use a systematic sampling scheme giving uniform coverage to the entire area, even though higher densities of burrows may be present in some areas than others. Resist the temptation to repeatedly return to places where ferrets have been seen. Some of the fringe areas of prairie dog colonies may have the largest populations of prairie dogs, and intuitive perceptions of habitat quality are not always reliable. Provide markers to assist with relocating ferrets and orienting the surveyor.

3. Diligently attempt to identify all ferrets. If a transponder cannot be read remotely, then try to capture the ferret. If some members of the team are more adept at capture than others, then consider using them as a dedicated "capture" crew whose job is to capture and identify ferrets rather than search for them. Occasionally, individual ferrets can be identified by unique physical characteristics that can be distinguished after capture or, even more uncommonly, without capture. Acceptable examples we have seen include deep scars, missing portions of ears, and missing toes. We do not consider differences in coloration and individual mask patterns to be sufficiently reliable for individual identification.

4. If individual ferrets are not identifiable, then we recommend a conservative approach to classifying them as separate individuals. Unless snow allows absolute separation of track sets, ferrets can be classified as separate individuals only if it was nearly impossible for an animal to have moved between the two locations during the time interval between sightings. For sightings separated by <500 m, the sightings must be simultaneous (fig. 4). For sightings separated by longer distances, we assumed a maximum speed of 6 km/h for a ferret, decreasing in a nonlinear manner with increasing distance. This maximum has been used to screen radio-telemetry data for errors (Breck and Biggins, 1997). We reduced the maximum speed to a low of 0.694 km/h with a separation of 50 km because the maximum documented movement of a ferret in a 3-day period was about 50 km (Biggins and others, 1999). Two sightings with distance and time separations that plot above the curves of figure 4 can be assumed to be separate individuals. This approach mandates substantial evidence for inclusion of animals into a population count. To avoid underestimation of population size for unmarked populations, a larger survey crew will be

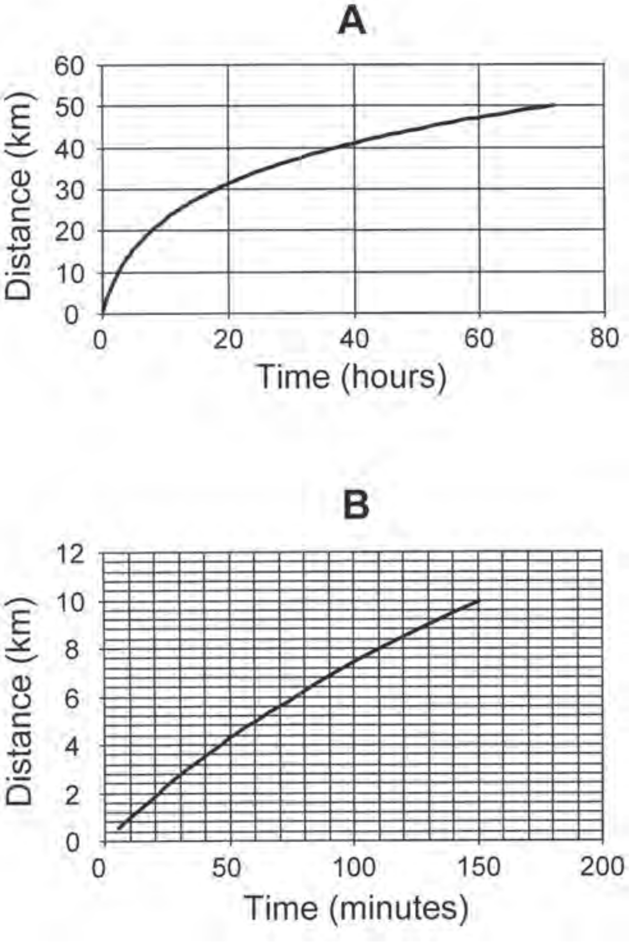

Figure 4. Minimum separations of distance and time needed to classify two sightings of black-footed ferrets (*Mustela nigripes*) as different individuals. Plot B is the lower portion of the curve in plot A, rescaled to provide better resolution. Separations of two sightings plotting above the curves can be considered separate individuals (e.g., two sightings 4 km apart separated by 30 minutes).

necessary (to increase the probability of simultaneous sightings of ferrets living in close proximity to each other).

5. A brief meeting should occur the morning following each spotlight search session to discuss results from the previous night. One important purpose is to assess the number of unique individuals that are likely represented by ferrets seen but not identified (using the criteria of 4 immediately above).

6. Use a standardized form with a map on the reverse side. Record all nonspotlighting periods (e.g., rest breaks) on the form, sketch ferret locations on the map, and place a marked flag at each ferret location. Use Global Positioning System (GPS) equipment to obtain coordinates of ferret locations, and record these coordinates on the data form (see appendix for examples of forms and checklists). Once coordinates and other necessary data have been collected, remove all flags.

7. Ferrets should be double marked before release with two PIT tags (anterior and posterior). At present, incompatibility among manufacturers requires that the ferret program adopt a single system. The tags and readers currently used in the ferret program are made by AVID® Microchip I.D. Systems (Folsom, La.). Transponder technology is developing rapidly, and other systems may be practical in the future.

8. Unmarked ferrets that are wild caught should be marked or re-marked if they have lost previous markings. Field anesthesia by a veterinarian or certified individual is necessary.

9. An annual report to the FWS should include a table listing all ferrets identified in monitoring surveys. Ideally, the table should be in a commonly used computer spreadsheet. For each ferret, the following accessory information should be provided:
   a. Studbook number and field identification number (telemetry number, site-specific wild-born animal number, PIT tag number, etc.)
   b. Sex
   c. Method of identification
   d. Date(s) of capture or identification
   e. Location(s) of capture or identification (Universal Transverse Mercator [UTM] coordinates from GPS receiver; include datum and grid zone)
   f. Observer(s)
   g. Date of original release (if applicable)
   h. Specimens taken (blood, fecal, parasites, etc.)
   i. Other data taken (weight, measurements, etc.)
   j. If previously unmarked wild-born kit, identify litter size and associated dam.

10. A standard release form (see appendix), filled out for each ferret released, should also be forwarded to the Black-footed Ferret Recovery Program Coordinator. As in 9 above, the forms can be tabulated and forwarded in spreadsheet form on a magnetic disk (see Plumb and Marinari [1996] for an example table).

Recommended Precautions—Legality, Human Safety, and Animal Safety

1. If using all-terrain vehicles (ATVs), heavy batteries used to power spotlights can change weight distribution and make the vehicles unstable.

2. Riders of ATVs should be certified if required by the employer. Night operation and use of a spotlight increase the difficulty. Special training should be provided on ATV safety and night use. Use appropriate protective gear and clothing.

3. Obtain all permits and notify appropriate authorities regarding timing and location of spotlighting activity. Spotlighting is prohibited or regulated in some States. A Federal endangered species permit will be required.

4. Listen to weather reports and be familiar with local conditions. Weather can change rapidly, and impending changes may not be obvious at night. Hazards include lightning, dangerously large hail, tornadoes, and disorientation at night, especially in snowstorms. These phenomena are not imaginary; spotlight searchers have had close calls with all of them.

5. Searchers should be fully familiar with their assigned areas, which may require a visit during daylight. A compass or personal GPS unit may allow a technician to avoid becoming lost during thick fog or heavy snowfall. Searchers should work in pairs when there is a threat of adverse weather.

6. The survey crew should be as well equipped as possible with two-way radios. For safety and efficiency, it is especially important to maintain frequent communication with individuals working in remote areas.

7. Landowners must agree (preferably in writing) to the activities being conducted on or around their properties and should be kept well informed of progress.

8. Respect property, whether public or private. Avoid rutting muddy roads, and follow applicable rules and procedures for off-road driving with ATVs or larger vehicles. If you inadvertently damage property (e.g., gates, fences, cattle guards), make any needed repairs or arrange to have them done.

9. Spotlights are disruptive, so minimize the observation time with intense white light. After locating a ferret, it should be observed in the periphery of the light beam, using the least illumination possible to maintain contact for necessary follow-up activities (e.g., transponder reading, trapping). Avoid repeated harassment of the same animal.

10. When trapping, do not separate a mother from her kits for extended periods. Although unusual circumstances may dictate either more lenient or more restrictive limits, we suggest limiting such separations to <24 hours during late July–September. Separations should be much shorter if it becomes necessary to trap an adult female (that has young kits) earlier in the season. Remember that a burrow blocked by a trap can separate the dam from her kits even if no ferrets are caught. Traps should be checked at least once per hour by approaching the trap and looking all the way into it. Closed traps should not be left in burrows (ferrets have been inadvertently caught in closed traps). Badgers and other predators can kill an entrapped ferret, and severe weather can cause hyperthermia or hypothermia.

11. Use properly maintained traps. Traps that are poorly maintained or misused have injured ferrets. For example, ferrets have received abrasions and lacerations when forcing their way through gaps at the back door, even though the doors were secured with clips. We recommend clipping or otherwise fastening each corner of the back door. Check for treadle sensitivity, protruding wires, broken welds, and bent parts. Poorly maintained traps may increase the amount of time spent harassing an animal if repeated attempts become necessary to catch it. Wrapping traps in pieces of wool blanket or burlap helps protect a captured ferret from wind and cold and seems to create a more enticing tunnel that may facilitate capture and keep the animal calm after capture.

12. Ferrets usually should be released into the burrow where they were captured and during hours of darkness whenever possible. If necessary, a ferret may be held in a cool location until the following night. A portion of a prairie dog can be given to any ferret that must be captured for handling or marking to help mitigate the stress of the procedure. If presented at the time of release, ferrets often will take these offerings into the burrow. Prairie dog remains may attract badgers or other predators, so their use should be judicious and closely monitored. If your site is within the known range of plague, we suggest precautions to avoid inadvertently feeding plague-contaminated carcasses (use prairie dogs from plague-free zones or those that have been properly quarantined).

13. Contact the Black-footed Ferret Recovery Program Coordinator for latest developments regarding trapping and handling ferrets, and refer to Thorne and others (1985) for additional details.

The best training for monitoring black-footed ferrets is assisting in an effort that is already underway. Persons who will be responsible for monitoring at a new reintroduction site should participate in monitoring at an existing site well before the new project begins.

Expanding Beyond the Minimum Standards

1. Groups of ferrets may be released sequentially at a site throughout extended periods (60 days or more). Spotlight surveys have been conducted 30 days after the last release (Montana and South Dakota) and 30 days after the midpoint of extended releases (Wyoming). For releases over relatively long spans of time, a solution might be to conduct more than 1 survey at about 30 days postrelease, treating groups of animals as separate releases.

2. Prior estimates of survival of released ferrets using spotlighting data were treated as minimum survival because ferrets may have remained undetected during surveys. With several searches repeated over a short time span (e.g., 2 weeks) true survival rate or population size may be estimable. Separate estimates of the probability of detection and accompanying variation could be investigated with repeated sampling within short time spans. The assumption of no emigration or other losses is problematic, so each complete search should be carried out quickly (one to three nights) and repeated as often as expedient.

3. As conditions permit, snow tracking should be used to augment spotlighting. Data collected by snow tracking may not be directly comparable to spotlighting data. Because maximum comparability through standardization across sites and years is an important consideration, snow tracking may supplement spotlighting but cannot replace it. Ferret scats have been collected during snow tracking, providing additional opportunities for evaluations of food habits (Sheets and others, 1972; Campbell and others, 1987) and for molecular genetic assessments.

4. Telemetric monitoring will most likely provide con-

structive feedback for management decisions if used during the first release at a new site, at sites with high rates of ferret disappearance, during a dramatic population decline, or in studies designed to test hypotheses having wide-scale implications (see also Biggins, Godbey, Miller, and Hanebury, this volume). In the interest of avoiding additional burden to a dwindling population, it may be tempting to reduce monitoring intensity (and eliminate telemetry) at a time when information is most desperately needed. The information gained through detailed studies during a crisis may be critically important for future success at that site and for the recovery program in general. A "failure" may be recharacterized as a success if enough is learned to avoid repetition of the event at that same site or at other sites. As with snow tracking, use of radio telemetry does not eliminate the need for the spotlight surveys.

5. The addition of a spring spotlighting survey, conducted as described above for the fall and summer surveys, provides a useful assessment of overwinter survival and an estimate of the breeding population of ferrets. These surveys are often conducted in March or April (Matchett, 1997).

Other Issues—Duration of Monitoring Program, Altering the Intensity, Monitoring and Research

If the ferret population is not yet near estimated carrying capacity but its growth is as expected or above, the minimum monitoring strategy should be adequate. Because there will be a need to know when a population may require augmentation, and when a population is doing so well that it can be a source of animals for other populations, annual monitoring at these minimum levels should be conducted for each year that ferrets are released and at least 2 years following the final release. A ferret population may be surveyed in alternate years if it has a positive growth rate or remains stable because of birth of kits at the site for 2 years following the final release and if the site will not be serving as a source for translocations of ferrets. The most intensive monitoring should be planned for the first few years of releases at a site when there are many questions and no established record of success, with decreases in intensity during subsequent years. If population growth becomes slow or negative, intensive monitoring again is appropriate to identify the problem(s). Increased spotlighting and/or radio telemetry may be needed in some cases. Other types of monitoring (e.g., for diseases such as plague and distemper; prairie dog abundance and habitat quality) are also needed, and their results help define the relative need for ferret monitoring. The situation predictably will be dynamic, calling for flexibility in program management. If some working groups have insufficient resources to respond rapidly to changes, the leadership in the national program may need to recommend reallocation of resources (e.g., funds authorized under section 6 of the Endangered Species Act, different priorities for research support) to sites in response to shifting needs. Even the minimum monitoring standards proposed above may need modification if (1) the entire program becomes dramatically more or less successful than at present, (2) funding radically changes, (3) available habitat becomes fully occupied by ferrets, and (4) new technology makes more efficient techniques available. We strongly recommend close communication between working groups and national program managers during the process of formulating site-specific monitoring plans.

The suite of methods described for monitoring black-footed ferrets has been used for both research and management applications, but the distinction between the two purposes is poorly defined. Many ferret releases in the near future probably will have a blend of learning objectives (implying research with indirect benefits to long-term recovery) and population establishment objectives (implying management actions with direct, short-term benefits). A single monitoring program often contributes to both purposes. For example, snow tracking in 1982–86 at Meeteetse yielded winter population estimates for ferrets, helping to track the welfare of the population in the immediate sense, and gave information on movements of animals and other aspects of ecology (Richardson and others, 1987). Used during releases of ferrets, radio telemetry has allowed relocation of animals that dispersed into unsuitable habitat and has enabled documentation of heavy losses of ferrets to predation, information with important short-term management implications. In several cases, the primary purpose of radio telemetry was to test hypotheses of differential survival and behavior of groups of ferrets produced and released under varying conditions (Biggins and others, 1999). The minimum spotlighting standards recommended above emphasize the immediate need to assess population attributes. Addressing other objectives probably will require a more intensive strategy, expanded by adding other methods and/or increasing the amount of spotlighting (spatially or temporally).

Radio Telemetry for Black-footed Ferret Research and Monitoring

By Dean E. Biggins,[1] Jerry L. Godbey,[1] Brian J. Miller,[2] and Louis R. Hanebury[3]

Abstract

By 1973, radio telemetry was regarded as an important potential tool for studying the elusive, nocturnal, and semifossorial black-footed ferret (*Mustela nigripes*), but fears of using invasive techniques on this highly endangered mammal caused delays. We began radio collaring ferrets in 1981. Use of radio telemetry on ferrets proved to be both challenging and rewarding. We document two decades of development and use that led to the present radio-tagging techniques and methods for radio tracking. The 7-g radio collar commonly used after 1992 was smaller and lighter, relative to mass and size of subjects, than collars used in studies of other *Mustela*. Other important developments were a Teflon® coating to shed mud, a highly flexible stainless steel cable for whip antennas, and a nondurable wool collar. Although collar-caused neck abrasions have continued to occur sporadically, a retrospective assessment of minimum survival rates for 724 reintroduced ferrets (392 radio tagged), using data from spotlight surveys, failed to detect negative effects of radio-collars. In a South Dakota study, ferrets that were found to have hair loss or neck abrasions when collars were removed did not exhibit movements significantly different from those of radio-tagged ferrets with no evidence of neck problems. Prototype transmitters designed for surgical implantation had insufficient power output for effective use on ferrets. Early attempts at tracking radio-tagged ferrets by following the signal on foot quickly gave way to following movements by triangulation, which does not disturb the subjects. The most effective tracking stations were camper trailers fitted with rotatable, 11-element, dual-beam Yagi antennas on 6-m masts. We used radio telemetry to produce 83,275 lines of data (44,191 indications of status and 39,084 positional fixes via triangulation) for 340 radio-collared ferrets during the reintroduction program. Tracking by hand and from aircraft augmented triangulation, allowing us to locate animals that dispersed long distances and enabling us to determine causes of mortality. Justifying further use of radio telemetry on black-footed ferrets requires careful consideration of costs and benefits.

Key words: black-footed ferret, collar, *Mustela eversmannii*, *Mustela nigripes*, radio telemetry, radio tracking, Siberian polecat, survival, triangulation

Introduction

Radio telemetry has been used as a tool to study vertebrates for more than 50 years (Kimmich, 1979) and *Mustela* since the mid-1970s (Erlinge, 1979). The technique is especially useful for re-locating individual animals that are highly mobile, secretive, and difficult to observe. Black-footed ferrets (*M. nigripes*) are among the most nocturnal of carnivores, and they are semifossorial, attributes that reduce our ability to monitor them with other techniques. Ferrets may be located with spotlights, a technique that is often employed for conducting annual surveys of their abundance (Campbell and others, 1985; Biggins and others, 1998a). Spotlighting, however, affects the behaviors of ferrets (Campbell and others, 1985), making it less attractive for the intensive monitoring that may be required for behavioral studies. Techniques must be matched to objectives, and the relative advantages and disadvantages of radio telemetry, spotlighting, and snow tracking for studying black-footed ferrets have been summarized elsewhere (Biggins, Godbey, Matchett, and others, this volume). This article addresses the challenges of applying radio telemetry to studies of black-footed ferrets, in part to help a potential investigator decide whether it is the appropriate tool for the goals of the project being considered.

Because of difficulties encountered by earlier researchers in studying this secretive species and because technologies were rapidly advancing, radio telemetry was recognized as a “vital” tool for future ferret investigations (commentary by E. Brigham in Linder and Hillman, 1973, p. 162). Erickson (1973, p. 156) emphasized a need to use radio telemetry on ferrets, lamenting that “the black-footed ferret is one of the least well known of all of the endangered mammals of the United States, despite 10 years of intensive research.” The anticipated importance of this tool was reflected in a primary objective of the first captive breeding program for

black-footed ferrets (commencing in 1971), which was “not to produce animals for release in the wild, but to learn more about . . . safe marking methods” and “means of following their travels and home range” (commentary by R. Erickson in Linder and Hillman, 1973, p. 26). These experiences of the 1970s motivated development of prototype transmitters for black-footed ferrets, but, by the latter years of that decade, no free-ranging ferrets could be found. Our use of radio telemetry on black-footed ferrets began in 1981 with the discovery of the last known extant population west of Meeteetse, Wyo. Our intent is to review the use of radio telemetry for black-footed ferret research during the subsequent two decades. There is a particular need to document the problems and our attempts to find solutions. Detailed discussions of hardware and methods that did not work seem as important as discussion of the triumphs, if only to provide a better starting point for those who might wish to engage in improving the techniques. We review the challenges of radio tagging these animals, methods used to gather data once they have been tagged, and methods for analyzing those data.

Radio Tagging Black-footed Ferrets

In a prophetic prediction of upcoming problems, Erickson (1973, p. 157) stated “There is no known way to safely develop and test methods of installing radio-transmitter harnesses on live ferrets in the wild.” Although the first transmitter packages intended for use on black-footed ferrets (fig. 1) were indeed tested on surrogate domestic ferrets (*M. putorius furo*; fig. 2) (C. Hillman and S. Martin, oral commun., 1980), problems developed when the collars were first used on black-footed ferrets at Meeteetse in 1981–82. Neck abrasions sometimes occurred with these 15-g collars, and they had low power output (table 1, version A-1), in part caused by the inefficient brass loop antenna that also served as a collar (fig. 1). The low power resulted in frequent loss of contact with subjects (Fagerstone and Biggins, 1986). Although a more powerful collar prototype was produced in 1982 (table 1, version B-1), it seemed too bulky for use on ferrets. That transmitter was attached to a harness, but tests on surrogate prairie dogs (*Cynomys* spp.) (fig. 3) were unsuccessful. The original packages were again used in 1982, but the brass loop collars were difficult to fit and collar loss was high (Fagerstone and Biggins, 1986). These first radio collars for ferrets transmitted on 164 MHz.

Figure 2. Early transmitter packages with tuned loop antennas (version A-1 of table 1) were tested on domestic ferrets (*Mustela putorius furo*). Photograph by U.S. Fish and Wildlife Service.

We also conducted comparative experiments with reception of signals emanating from underground transmitters on 30 MHz and 164 MHz, reasoning that the longer wavelengths would better penetrate soil. The lower frequencies performed no better than the higher frequencies during underground trials, but problems with transmitting and receiving antennas were exacerbated with the lower frequencies (lower frequencies need larger antennas for efficient transmission and reception). All subsequent transmitters were on 164–165 MHz at frequencies licensed to the U.S. Department of the Interior.

Early in 1983 we submitted specifications for a new transmitter collar to manufacturers of wildlife telemetry equipment, requesting their assistance in producing an improved transmitter package. Prototypes from three of the five companies that responded exceeded dimensional or weight limits. Two units (table 1, version D-1, fig. 4; table 1, version C-1, fig. 5) seemed satisfactory and were used on 10 black-footed ferrets in August 1983 (Fagerstone and Biggins, 1986). Reception range was several times greater with model D-1 than with model A-1 used in 1981–82. During 1983, however, breakage of the whip antenna was common, and sometimes accumulations of clay resulted in large increases in mass and dimensions of the transmitter package (fig. 6). The accumulations of clay likely were partially responsible for some neck injuries. Various treatments and coatings, including polished acrylic (fig. 7A), wool (fig. 7B), and Teflon® (DuPont, Wilmington, Del.) heat-shrink tubing (fig. 8), were used in laboratory trials and on prairie dogs and ferrets in the field during 1983 and 1984 to alleviate the mud accumulation problem (Fagerstone and Biggins, 1986). The Teflon tubing solved the problem of mud accumulation; however, its slippery surface seemed to

exacerbate collar loss, and there were several instances of neck abrasions.

Continued problems with collar loss in 1984 motivated additional investigation and development of transmitter attachment methods for ferrets. Disease outbreaks in Meeteetse prairie dogs and ferrets (Forrest and others, 1988; Ubico and others, 1988) ended all hope for continued research on that free-ranging population of ferrets; however, the ensuing captive breeding program and its ultimate goal of reintroductions underscored the importance of improving radio telemetry for ferrets. In trials conducted in the spring of 1985, two of three free-ranging black-tailed prairie dogs (*Cynomys ludovicianus*) developed neck sores when fitted with old-style ferret collars made of vinyl-impregnated cloth but did not seem adversely affected by neckbands of wool ($n = 4$) or leather ($n = 4$). Prairie dogs gained 40 percent in mass during a 3-month period. Wool collars sewed with cotton thread often wore sufficiently to be lost by prairie dogs in 3 to 6 months. Thus, a black-footed ferret with a wool

neckband would not be collared permanently if its radio failed prematurely and the animal could not be relocated for collar removal.

One of the goals of research initiated in 1988 on Siberian polecats (*Mustela eversmannii*) and other surrogate species was to advance our proficiency in radio tagging and radio tracking *Mustela* before reintroductions of black-footed ferrets. Studies of captive Siberian polecats and of reproductively sterilized polecats released into prairie dog colonies in Colorado and Wyoming provided opportunities to develop and test equipment. Radio collars made of natural materials were first tested on 13 captive polecats at the National Zoo's Conservation & Research Center, Front Royal, Va., during September 1989. Neckbands were made of leather or wool instead of the vinyl-coated fabric used previously. Collar retention was the primary reason for preliminary testing of radio collars on captive ferrets. Wool and leather collars are somewhat elastic, and the >10 percent stretch of these materials might allow animals to slip out of the collars. Overlapping ends of wool and leather collars were glued with contact cement. The transmitter package for polecats weighed about 10 g, had a 15.2-cm whip antenna (table 1, version D-2), and was attached to a 1-cm-wide wool collar with vinyl tape (not Teflon). The 2-stage, 3-V transmitter had a mercury switch that triggered change in pulse rate, resulting in pulse intervals of about 0.9–2.4 seconds, with pulse interval inversely proportional to activity of the animal (as sensed by motion of the transmitter), and a pulse width inversely proportional to pulse interval to maintain consistent and predictable current drain. Battery longevity was about 59 days.

Both wool and leather collars were removed by some captive animals, but in most cases the shed collars were in poor condition. Captive polecats were housed in family groups and tended to chew and pull on each other's collars causing rapid wear that we did not expect to occur under field

Figure 8. A 13-g transmitter package (version D-1 of table 1) from Wildlife Materials, Inc. (Murphysboro, Ill.), with Teflon tubing covering most of the acrylic potting material (used on black-footed ferrets [*Mustela nigripes*] during 1984). Photograph by D. Biggins.

conditions. Wool collars were no more likely to be pulled off than were leather collars, but wool collars wore more quickly. Because the "breakaway" feature of wool was desirable, the wool collar was selected for testing on the released animals to evaluate retention and irritation. Under field conditions, only 1 of the 13 polecats removed its collar, but that animal did so twice. Whip antennas broke on collars worn by two polecats. One antenna became completely severed after 10 days on the animal, and a radio recovered from a dead polecat had several broken strands in its antenna wire. Our simple solution was to use slightly heavier wire and an extra layer of heat-shrink coating extending 1 cm above the point where the antenna protruded from the radio capsule. No sign of worn hair or neck abrasion was noted on recovered polecats; however, there were only a few days of wet weather during our polecat release study, and the soil was sandier than soil at the Meeteetse black-footed ferret study area. Therefore, the potential for mud accumulation on radio collars was not fully assessed. During a short wet period, a small amount of mud was found on the collar of one recaptured polecat, but the mud fell away easily. Poor survival of polecats hampered the evaluation of radio-collar performance in that study (Biggins, 2000a).

Additional polecats released in 1990 (*n* = 44) accumulated about 600 animal days wearing the type of radio collars described above (but with the modified antennas), combining the time that animals carried radio collars during arena conditioning with monitoring time after release. The wool collars continued to function well overall. One collar deteriorated rapidly and was lost from a polecat after only 2 weeks, perhaps because that animal (no. 34, wild caught in China) was exceptionally active. Several other animals lost collars, likely in part because of rapid weight loss after release, particularly with obese animals (Biggins, 2000a). One instance of neck abrasion was noted, and again it was with animal no. 34. That animal was recollared after losing her first transmitter collar; perhaps the tendency was to fit the second collar too tightly because of the prior loss.

The polecat from China (no. 34), radio tracked until the study ended, lost 50 percent of her body mass and her radio collar during the first several weeks postrelease. Perhaps that scenario helps explain the high rate of lost radio contact with wild-caught polecats (3/5 versus 5/39 for captive-bred polecats). Other factors also can cause loss of radio contact. Two recovered radio collars were damaged, presumably by the teeth of coyotes (*Canis latrans*). The signal from one of those collars was barely audible above ground, even at short range (<100 m), suggesting the possibility of complete radio failure from bites of coyotes or badgers (*Taxidea taxus*). Radio signals also can be lost when animals are in burrows >2 m below ground. Because loss of radio contact could have been a result of predation, dispersal, or premature transmitter failures, functional longevity for collars could not be estimated.

Similar versions of these transmitters with wool collars also were used to study free-ranging Siberian polecats (fig. 9) (Zhou and others, 1994) and alpine weasels (*Mustela altaica*) in China (fig. 10). Collars of wool functioned well generally, but premature collar loss and occasional neck abrasions continued to be problems. Collar loss was especially common in the alpine weasel study (Wei and others, 1996). The polecat transmitter packages with variable pulse rates used in China and the United States produced easily interpreted activity data.

Figure 9. Additional collar tests (version D-2 of table 1) were conducted on a subspecies of free-ranging Siberian polecat (*Mustela eversmannii dauricus*) in Inner Mongolia, China. Photograph by D. Biggins.

Figure 10. We used smaller transmitters with wool collars to study alpine weasels (*Mustela altaica*) in Qinghai, China. Photograph by D. Biggins.

Because of the effective combination of wool collars and activity-type transmitters used on polecats, this 10-g unit by Wildlife Materials, Inc., (WMI, Murphysboro, Ill.) and a similar variable-pulse rate model by AVM Instrument Company, Ltd., (Colfax, Calif.) (table 1, version A-2) were adopted for monitoring 37 of 49 black-footed ferrets released during the first reintroductions in 1991 at Shirley Basin, Wyo. (U.S. Fish and Wildlife Service, 1992). Collars were worn by ferrets for 2–4 weeks before they were released, allowing prerelease observation of animals but also expending 40–68 percent of the expected battery life and producing noticeable wear to the wool collars.

Fluctuations in mass of animals appeared to create problems. Ferrets from the Henry Doorly Zoo (Omaha, Nebr.) were 26 percent heavier when collared than were their wild counterparts at Meeteetse ($P < 0.001$) and were 37 percent heavier at 5 days postcollaring. Seven of the zoo ferrets developed neck sores while being held in cages, perhaps because of the increasingly snug fit of the collars as the ferrets gained mass. Ferrets raised at the Wyoming Game and Fish Department facility were not heavier than Meeteetse ferrets prerelease. We accumulated 460 animal days of postrelease telemetric monitoring on the 37 ferrets. Loss of mass postrelease (Biggins, 2000a) likely loosened the fit of collars and may have exacerbated premature collar loss that occurred in nine known instances involving six individual ferrets (ferrets were sometimes recollared). One free-ranging ferret had a neck laceration when recaptured, but other injuries confused determination of the cause(s). There were two known cases of mud adhering to the vinyl tape used to attach the transmitter package to the collar.

Continued problems with collars in 1991 resulted in a more conservative approach to collar configurations used for ferret studies in subsequent years. Beginning in 1992, ferrets were collared with smaller transmitter packages, and Teflon heat-shrink tubing became the standard method for attaching the transmitter to the double- or triple-layered wool collar (fig. 11). The WMI transmitter had a 20.3-cm flexible steel whip antenna (table 1, version D-3). We located an improved type of stainless steel wire for whip antennas (designed for operating prosthetic limbs) that further reduced the problem of breakage resulting from metal fatigue. The 1.5-V battery gave an estimated 45–150 days of transmitting, depending on power output desired. The completed package weighed 6.0–7.2 g (usually <1 percent of the subject's mass). We believe that miniaturization of the transmitter-collar assembly reduced problems of collar loss and neck abrasion in black-footed ferrets. See appendix for instructions on final assembly of these collars and the procedure for fitting them to ferrets.

Figure 11. Fitting a lightweight (6–7 g) transmitter collar (version D-3 of table 1) to a black-footed ferret (*Mustela nigripes*). This style of collar has been used since 1991. Photograph by R. Reading.

Serious neck injuries may be caused by improper fit of radio collars; abrasions on radio-collared black-footed ferrets in 1991 fueled controversy over effects of collars on survival of ferrets. Oakleaf and others (1993), using data generated from spotlight searches after the second ferret release in 1992, stated that "survival indices are significantly ($P = 0.002$–0.055) greater for black-footed ferrets released without telemetry compared to ferrets released with telemetry collars." These authors presented four criteria that should be met to enhance comparability of collared and noncollared groups in future studies. Data for their analyses were generated under conditions that violated two of their criteria, similarity in habitat quality and equal accessibility for spotlight searches in areas where radio-collared and noncollared ferrets are released. Radio-collared ferrets were released on lower quality habitat, as measured by densities of prairie dog burrows, than were noncollared ferrets, and the areas with collared ferrets were less easily searched via spotlighting. Prior recognition of the possibility of confounding can be inferred from the hypothesis generated before the 1992 release of ferrets, which stated that "survival of ferrets released in best habitat, without telemetry and with good logistics for spotlight surveys is higher than survival in habitat that is possibly less than the best, with telemetry, and possibly poorer conditions for spotlighting" (B. Oakleaf, quoted in Miller and others, 1996, p. 129). Regarding habitat quality, mounting evidence demonstrates a negative correlation between ferret dispersal and density of prairie dog burrows (Biggins and others, 1999; Biggins, 2000b), and ferrets prefer areas with high burrow density (Biggins, Godbey, Matchett, and Livieri, this volume).

Confounding of collar effect and other variables was problematic in the 1992 sample involving 89 ferrets but became less troublesome as sample size increased because the potentially confounding variables were not consistently associated with the same primary treatment groups. Thus, it may be revealing to examine a much larger data set of reencounters, resulting from spotlight surveys about 1 month postrelease, for 724 ferrets released in four States during 12 years (table 2). For all States except Wyoming, cage-reared ferrets were excluded from the analysis because ferrets that lack preconditioning in outdoor pens have relatively poor survival rates (Biggins and others, 1998a). We could not categorize rearing status for some of the ferrets released in Wyoming; thus, we pooled rearing categories in Wyoming (similar to the analysis of Oakleaf and others, 1993). A multivariate general model (with site-year and mark category) and competing nested submodels were evaluated with program SURVIV (White, 1983). Comparisons of Akaike's Information Criteria (AIC) associated with these models (table 3) favored either the submodel that pooled collared and noncollared ferrets (AIC = 52.86) or the general model (AIC = 51.14). Not surprisingly, reencounter rates (the product of probabilities of survival and capture) for sites-years were likely different. Although

evidence was somewhat equivocal regarding collars, the most parsimonious model of the two with low AIC values suggested no effect of collars (fig. 12). Regardless of improvements in sample size and reduced confounding potential, this remains a post hoc analysis of data from experiments designed to test other hypotheses. Interactions are probable (fig. 12) and the unbalanced design (table 2) allows numerous possible explanations to account for the disparate results for different sites and years. Nevertheless, these data do not support the contention that radio collars negatively affect reencounter rates of released black-footed ferrets. Perhaps cases of management intervention enabled by radio telemetry help compensate for potentially negative influences of collars. On a few occasions, ferrets that dispersed from suitable habitat were captured and translocated; other interventions (also rare) included capture, rehabilitation, and rerelease of ferrets that were injured or in poor condition.

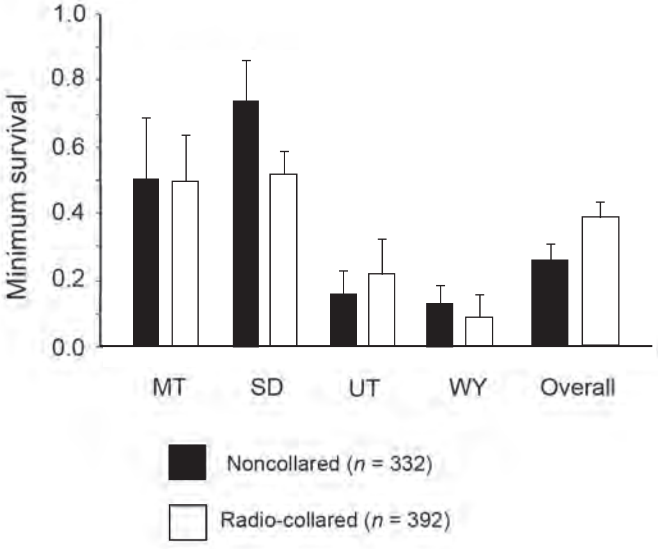

Figure 12. Minimum survival rates of preconditioned black-footed ferret (*Mustela nigripes*) kits at about 1 month postrelease.

In a study of translocated ferrets conducted in South Dakota in 1999 (Biggins and others, 2000a), neck abrasions that ranged from minor hair loss to a case of severe ulceration were noted on 10 radio-tagged black-footed ferrets (of 36 released) when animals were reobserved during the study or recaptured for collar removal at the end of the study. A categorical variable (abrasion, no abrasion) for neck condition was evaluated during statistical modeling to assess movements and dispersal of the primary treatment groups (released captive-reared versus wild-born ferrets). There was no evidence that neck abrasions affected any of the attributes of movements examined ($P > 0.19$ for all models), even though the experimental design and statistical analyses were sufficiently powerful to detect significant effects of several other variables.

In summary, collar-caused mortality of ferrets has not been documented, and there is no evidence of negative effects of radio telemetry on ferret populations or average behaviors within groups of ferrets. Nevertheless, collaring can at times negatively impact individual ferrets. Moreover, it seems best to assume, even without the latter evidence, that an unnatural protuberance of any sort will influence a free-ranging animal's behavior to some degree, even if that influence is not detectable statistically. Such influences may be acceptable, particularly if it can be reasonably assumed that they equally affect all treatment groups of an experiment. Decisions on whether or not to use this monitoring tool may rest with cost/benefit analyses. If information potentially gained could enhance success of future conservation of the ferret, risk to individuals may be warranted. The arguments, however, appear similar to those discussed with reference to releasing adult ferrets (Biggins, Godbey, Livieri, and others, this volume), wherein "some conservationists and ethicists may justify extreme means to achieve the goal of preservation and recovery" of a species, while "others may set inviolate moral standards regarding the welfare of individuals."

Compared to other recent studies of *Mustela* that have involved radio telemetry, our present collars have rather conservative dimensions and mass. Considering *Mustela* of sizes similar to black-footed ferrets, 27-g and 25-g collars were fitted to feral domestic ferrets in New Zealand (Moller and Alterio, 1999; Byrom, 2002), collars of 25–35 g were placed on European polecats (*M. putorius*) in Italy (Marcelli and others, 2003), and endangered European mink (*M. lutreola*) were tagged with collars of about 13 g in Spain (Zabala and others, 2003). Collars weighing 10 g (likely 4–6 percent of body mass) were placed on stoats (*M. erminea*) in New Zealand (Moller and Alterio, 1999). Although Jedrzejewski and others (2000) tagged least weasels (*M. nivalis*) in Poland with collars of only 3.5–4.5 g, that mass was about 4 percent of the body mass of their subjects. Realizing the sensitivity of these animals to handling and collaring, the latter investigators placed the weasels into an enclosure for several days of observation before final release at the location of capture. We are aware of problems of collar loss and neck abrasion caused by radio collars in other studies of radio-tagged *Mustela*, although discussions of such difficulties are seldom published.

Problems with collars precipitated evaluations of intraperitoneal and subcutaneous implants for black-footed ferrets. Surgically implanted transmitters have been used effectively in several other mustelids such as river otters (*Lutra canadensis*; Hoover, 1984), badgers (Minta, 1993; Goodrich and Buskirk, 1998), and American mink (*Mustela vison*; Stevens and others, 1997). In 1985, we solicited prototype implantable transmitters suitable for ferrets from radio-telemetry equipment suppliers. Two of these units were designed for intraperitoneal use (table 1, versions D-5 and E-2), and a smaller unit (table 1, version D-4) was to be used subcutaneously. All had disappointingly low power output, leading us to believe that the problems we had in 1991 with loss of contact with ferrets would be worse with the implanted transmitters. Power output of the implants was initially lower than even that of the first radio collars used (table 1) and could be expected to be further degraded after implanting by signal attenuation caused by the ferret's body. Thus, we did not proceed to the next planned step in tests, which was to surgically implant the transmitters into surrogate Siberian polecats.

We did, however, use intraperitoneal and subcutaneous implants in American badgers at the Meeteetse study area in 1984. The dorsally implanted subcutaneous units with 15.2-cm implanted whip antennas radiated more powerful signals than did intraperitoneal units in the same animals, but abscesses that developed around the subcutaneous transmitters resulted in their premature loss. Compared to signals from the radio-tagged ferrets, which were then carrying relatively powerful transmitters (table 1, version D-1), signals from the subcutaneous implants in badgers were about as easily received from our fixed stations, but the intraperitoneal implants in badgers were much more difficult to track. Allowing that technology might have improved during the subsequent decade, we repeated the process of acquiring prototype implantable transmitters for ferrets in 1997, with generally similar results. Relatively poor reception range is a well-known attribute of implantable transmitters, in part because of the compromises necessary with transmitter antennas, which can translate into reduced precision and accuracy of data (Koehler and others, 2001). In our case, low power output resulted in rejection of implant technology before it was necessary to weigh the additional risks and costs of the surgeries needed for implanting and removing the transmitter. It also would have been necessary to consider the possible impact of implants on fertility of females and the possibility that implanted ferrets might not be locatable when it was time to remove the transmitter.

Radio-tracking Strategies

We quickly realized after radio tagging the first black-footed ferret in 1981 that signal-following techniques using hand-held tracking equipment were unlikely to generate the type, quality, and volume of data we were seeking. Much time was wasted searching for the subjects given the combination of relatively inefficient receiving antennas and low power output from the transmitters. Aside from the partial solution of developing more powerful transmitters (discussed above), it also was necessary to use much more directional and sensitive receiving antennas in order to maintain contact with the ferrets. Also, our signal-following attempts at night often appeared to disturb the ferrets. Thus, we decided to develop several stations of varying mobility equipped with larger antenna arrays from which tracking could be remotely accomplished via triangulation. Camper trailers with dual-beam 11- or 12-element, rotatable Yagi antennas (fig. 13) became the mainstay of the tracking system, augmented by more mobile truck-mounted receiving equipment (fig. 14). The relatively high receiving efficiency of these stations resulting from the larger antennas was further enhanced by increasing the heights of the arrays with masts of 4.5–6.0 m and by placing the stations on hilltops whenever possible. Although reception range was highly variable for these stations and the transmitters that were developed later (table 1, version D-3), we commonly radio-tracked ferrets at distances of 0.5–2.0 km and received signals from as far as 26.0 km on occasion (Biggins and others, 1999).

Knowing the exact locations of stations is a prerequisite for accurate triangulation. These data were produced (in Universal Transverse Mercator coordinates) by using traditional survey techniques (transit and chain) in the 1980s, followed by location data from a differentially corrected Global Positioning System in later years. Meticulous accuracy testing of each station improved the data in two ways. First, such tests allowed assessment of bias patterns inherent in each station and development of correcting algorithms to improve accuracy of data during processing. Second, the residual variation in bearings from stations, after bias was corrected, allowed estimates of accuracy to be associated with each estimated location for a ferret. Tests were conducted by contrasting telemetric bearings to 60–100 beacon transmitter locations surrounding the tested station with a set of known bearings to those beacon locations measured with a surveyor's transit (fig. 15). We employed a split sample technique to analyze test data, using half of the sample to derive the bias corrections and the second half to assess residual variation after the corrections were applied (fig. 16).

Figure 13. Camper trailer fitted with rotatable, 11-element, dual-beam Yagi array, used to radio track black-footed ferrets (*Mustela nigripes*) at the Meeteetse, Wyo., study area in 1983–84. Photograph by D. Biggins.

Figure 14. Truck-mounted, collapsible, 5-element Yagi array used to radio track black-footed ferrets (*Mustela nigripes*) at Meeteetse, Wyo., during 1982–84. Photograph by D. Biggins.

A second prerequisite for accurate triangulation is the ability to reference bearings from the antenna. Bearings can be usefully processed only when they are relative to a known

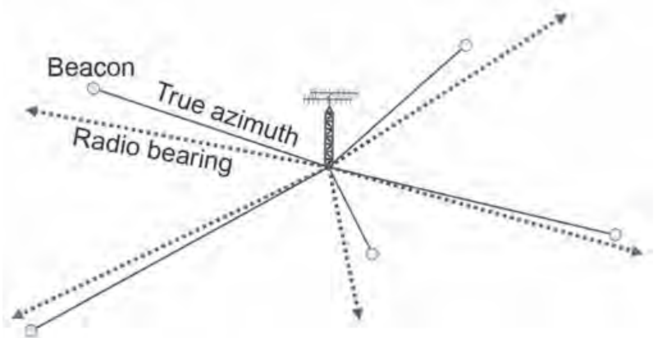

Figure 15. Accuracy testing and referencing involve comparison of true azimuths and radio bearings to beacon transmitters.

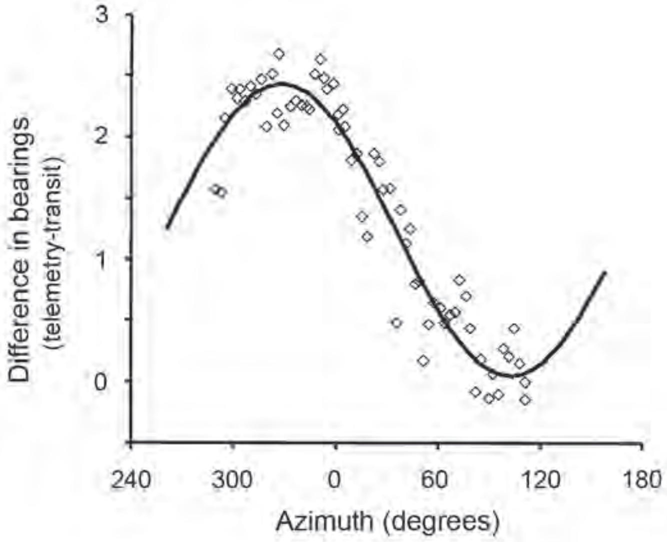

Figure 16. An accuracy test done at station 4, UL Bend National Wildlife Refuge, Mont., 1994. In this case, bias was corrected by using a formula defining the sine curve plotted. Residual variation produced a bias-adjusted accuracy estimate of ±0.63º (90% confidence) for future bearings from this station.

entity, such as grid north. One could simply align the main beam of the antenna to north with a compass and set the compass rose to zero. This method is rather crude (White and Garrott, 1990); at least two problems cause variable results. First, the physical and electronic alignment of antennas is seldom absolutely parallel. Second, there is considerable variation in the electronic aiming (fig. 16). If one could successfully get the aim exactly right at one particular point on the compass rose, then it would still not be correct for many other points around the compass rose. Some sort of averaging is needed. To solve these problems, we used reference transmitters placed at known points in the study area. Actual azimuths to the beacons were known for each station and were compared to the telemetric bearings to those transmitters (fig. 15), taken at the beginning of each tracking session. The compass rose inside a station was set so that zero was approximately at grid north (e.g., using a compass), and then readings to multiple beacons were used to provide an average correction that was applied to each subsequent bearing on an animal. Bias adjustment was applied before the referencing correction was made, the same as the process used when animals were tracked. Because the accuracy of this procedure affects all subsequent data, we cannot overemphasize the care needed in referencing. It would be nice to have many beacon transmitters (e.g., 50)! In practice, we used three to six beacons to avoid allowing referencing to become the dominant feature of a tracking session.

Although it is possible to plot triangulation data from pairs of these stations directly on maps to ascertain the whereabouts of the ferrets being tracked, it is more accurate and faster to process these data via computer. Advantages of conducting at least some of this processing while radio tracking include the following: (1) station selection can be adjusted as animals being tracked move about; (2) radio-tracking errors can be detected in time to correct them; (3) instances of mortality can be recognized quickly, resulting in better diagnoses of causes; (4) ferret dispersal can be detected in time to allow remedial action, if desired; and (5) in the case of lost radio contact, the last location calculated gives a starting point for searches. A computer program written by one of us (DEB) to accomplish these field processing tasks assisted the technicians with radio tracking ferrets at Meeteetse. The program was used on a programmable calculator in 1982 and was adapted to the first laptop computers that became widely available in 1983. That program evolved into TRITEL (Biggins and others, 2000b), which has been repeatedly modified since 1983 to accomplish referencing and bias corrections, convert azimuth data into coordinates, calculate error estimates for each telemetric fix (fig. 17), and store resulting data.

Procedures for radio tracking and processing data are detailed in a separate report (Biggins and others, 2000b). We have relied on intensive triangulation from these kinds of stations to produce large volumes of data. Although we have at times recollared ferrets to extend data gathering over several months, all telemetric studies were relatively short term. To monitor reintroductions, ferrets often were radio tracked for just 2–4 weeks postrelease, but stations were usually occupied during all hours of the day or during all hours of darkness, with fixes generated by occupants at two or more stations coordinating their tracking with two-way radio communication. Intensity of re-location for individual ferrets varied (3–60 minutes between consecutive fixes on an individual), depending mostly on how many individual animals were being monitored. During the reintroduction phase of black-footed ferret recovery (1989–2000), we used this tracking strategy

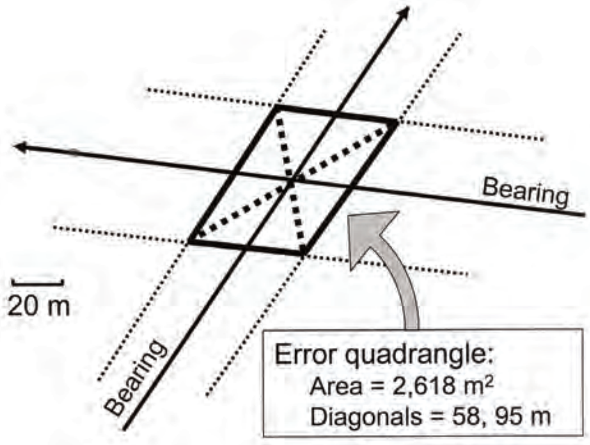

Figure 17. An example of a telemetric fix and error quadrangle (black-footed ferret [*Mustela nigripes*] no. 26, South Dakota, 10/23/97, 0148 h) produced by intersecting bearings and their associated error arcs from two tracking stations.

to monitor 340 radio-tagged ferrets and polecats, accumulating 83,275 lines of data that included 44,191 indications of status and 39,084 estimates of location (fixes). Data on status demarked beginning and ending points of tracking sessions, activity of animal (active, inactive) as determined by variation in signal strength, and pulse interval records when transmitters with variable pulse rates were used. Status data were recorded with fixes but were the only data recorded when triangulation was not possible (e.g., when only a single station received an adequate signal).

Radio-telemetry data from triangulation allows many options for analyses (summarized by White and Garrott, 1990). For black-footed ferrets, we have used radio telemetry to examine survival rates (Biggins, 2000a), linear movements (Biggins and others, 1999), dispersal (Biggins, Godbey, Livieri, and others, this volume), habitat preferences (Biggins and others, 1985; Biggins, Godbey, Matchett, and Livieri, this volume), indices of spatial use (Biggins and others, 1998b), and activity cycles (Biggins and others, 1986; Biggins, 2000a). The examples noted above are not exhaustive, and other options for use of the large data sets generated during multiple studies are currently being pursued. We believe that several features of analyzing telemetric data for ferrets, however, are worthy of emphasis here.

First, the inevitable errors that occur during triangulation must be detected and eliminated to the extent possible. Our system for handling data from triangulation, consistent with a pattern noted by Kenward (1987), has resulted in a series of custom computer programs for manipulating the output from TRITEL and screening for errors (Breck and Biggins, 1997). Similar to the BIOCHECK routine of White and Garrott (1990), our error screening involves searches for nonsensical data entries (e.g., unreasonable dates or times) and for data that fall outside limits set by a priori knowledge of ferret behaviors (e.g., maximum speed of movement). Errors are either corrected by referral to original data sheets, or offending lines are removed.

Second, estimates of ferret locations derived from triangulation are subject to direction-finding variation, as noted above. Estimates of such error associated with each fix (“error quadrangles” when two stations are used) are stored with each fix when TRITEL is used to process bearings. Our error screening process removes data lines with error estimates exceeding specified limits for lengths of diagonals or area of the quadrangle. Just as importantly, we have used these attributes of error as covariates in multivariate statistical analyses and often retain them in statistical models as “control” variables even if their estimated effect is small or not statistically significant. Although tracking error is nuisance variation when one is attempting to assess other treatments, it often accounts for significant variation (Biggins and others, 1998b, 2000a; Biggins, 2000a). If, however, a response variable is already known to be positively correlated to tracking error, then the use of tracking error as a covariate is not warranted. An example is dispersal. Because error is in part a function of distance separating station and subject, sizes of the error quadrangles increase as ferrets disperse away from tracking stations. Unlike other movements within the monitored area, radio-tracking error should not be used to explain variation in dispersal by ferrets because increased tracking error is an expected consequence of dispersal.

Third, the ferret data we have generated are serially correlated because of short interfix intervals; each telemetric fix cannot be considered independent (Swihart and Slade, 1985). The level of detail present in our data sets allows powerful behavioral comparisons (see examples cited above), but caution must be exercised in analyzing these data when independent observations are required (e.g., home range estimation; see White and Garrott, 1990).

The close association between black-footed ferrets and prairie dog colonies facilitates the radio tracking of ferrets from fixed tracking stations. Ferrets often remain within predictable boundaries where radio tracking coverage was nearly complete with careful placement of multiple stations (e.g., the Montana study of Biggins, Godbey, Matchett, and Livieri, this volume). Nevertheless, if we would like to monitor every animal in our sample with equal intensity and accuracy, triangulation from fixed stations is problematic (not unlike data from any other method of radio tracking or monitoring). Signal quality and accuracy of fixes vary with range and topography, and positioning of stations interacts with these factors to create uneven trackability of animals throughout any study area. The movements of some animals may be described more accurately and completely than the movements of others, and probabilities of detecting mortality cases may vary accordingly. Animals that disperse away from fixed stations may be tracked with lower intensity, lower accuracy, or not at all. Attributes such as cumulative movements are affected by frequency and accuracy of relocations. The consequences can be serious if the goal is to characterize the behaviors of the species. When comparing treatment groups (e.g., sexes, ages, rearing treatments), the consequences are more benign if we can reasonably assume that animals are distributed in the study area in such a way that members of each group are about equally trackable on average. The possibility of group-specific biases should be carefully considered for each case. For example, if dispersal is the attribute of interest, it may or may not be logical to rely on data from fixed-station triangulation. If dispersal distances have been artificially truncated by reception range of the tracking system, power of a comparative experiment may be reduced and dispersal distances will be underestimated to the greatest degree for groups whose members tend to disperse most frequently and farthest. Nevertheless, radio tracking from fixed stations has enabled us to detect significant between-group differences in dispersal (Biggins and others, 1998b, 1999). A germane statistical adage might be “if the tree falls, the axe was sharp enough” (Martin and Bateson, 1990, p. 126).

We have augmented triangulation with hand tracking, automated signal monitoring and data logging, and tracking from aircraft. Hand tracking, usually with a hand-held receiver and a 3-element Yagi antenna, was often used to investigate ferrets whose transmitters (a) were in unusual locations, (b) had moved rapidly, (c) had not been detected for long periods, (d) were stationary above ground at night, or (e) were above ground during daytime. These circumstances often led to re-location of ferrets that had dispersed (fig. 18) or to ferrets that had been killed by predators (fig. 19; Biggins, Godbey, Livieri, and others, this volume). We attempted to visit the location of the last fix if contact with a transmitter was lost for 2 or more days; listening for a radio signal while walking a narrowly spaced grid (ca. 2-m spacing) sometimes allowed detection of the transmitter belowground to depths of >4 m. Signal strength was correlated with depth of the transmitter; weakest signals could be received only when the operator was almost directly above the transmitter with the Yagi antenna pointing vertically downward (Biggins, 2000a). Signals seldom emanated from burrow entrances (contrary to the predictions of some electronic engineers). Remains of badger-killed ferrets were located by careful searches and excavated (fig. 20). Lost contact with transmitters also precipitated aerial searches at some sites. Each aircraft was equipped with a pair of 4-element Yagi antennas (affixed to each wing strut) and a switch to allow the operator to listen to the signal from each antenna separately. Homing on the source of a signal was accomplished by equalizing the null from each antenna (Gilmer and others, 1981). Radio-tracking flights helped locate ferrets that dispersed to different prairie dog colonies, especially when the flights were at night when ferrets are

most active above ground (Biggins and others, 1986; Biggins, 2000a). The most common product of flights, however, was detection of lost collars and cases of aboveground predation on ferrets that had dispersed (or their transmitters had been dispersed by the predator) beyond signal reception range of tracking stations. In short, these follow-up techniques, although arguably less technologically demanding than the radio tracking by triangulation, have provided the critically important details on fates of animals that other strategies cannot produce.

We used signal monitoring both with automated chart recorders and with computer loggers in attempts to collect information on aboveground activity of ferrets and polecats (Biggins, 2000a). The technique was useful to supplement data from triangulation, particularly on animals that were beyond the boundaries of the area that could be effectively monitored by tracking stations; however, the relative insensitivity of automated systems to detection of weak signals, coupled with the large activity areas of black-footed ferrets, limits the utility of automated tracking for ferrets.

Summary

The wide range of problems and accomplishments accompanying the use of radio telemetry on ferrets provides an opportunity for both detractors and proponents to present powerful arguments. Although success was never close to total, failures were not devastating to data or the ferrets. We would like to reemphasize that radio telemetry is an expensive and labor-intensive method for monitoring black-footed ferrets and that attaching radio transmitters to ferrets poses risks to the animals. It is essential, therefore, to carefully consider the objectives of a study to ascertain whether other tools would suffice. Justifications for use of radio telemetry on ferrets include unexplained lack of success in establishing a ferret population and tests of hypotheses that have large-scale management implications and require behavioral information. Cost/benefit analyses regarding use of telemetry should include as costs the potential future losses of ferrets if a perceived need for information remains unfulfilled. In some cases, short-term recovery objectives may become subordinate to learning objectives that could advance long-term recovery goals.

Acknowledgments

We thank the electronics laboratory of L. Kolz, of the former Denver Wildlife Research Center (U.S. Fish and Wildlife Service), for testing power output and other attributes of prototype implant and collar-mounted transmitters. Evaluations of prototype transmitters would not have been possible without sincere efforts and special attention of engineers and technicians at Advanced Telemetry Systems (Isanti, Minn.), AVM Instrument Company, Ltd., Custom Telemetry and Consulting (Watkinsville, Ga.), Telonics, Inc., and Wildlife Materials, Inc. We appreciate the dedication of the many technicians over a 20-year period that assisted with setting up, testing, and operating tracking stations.

Appendix. Notes on Radio Collaring Black-footed Ferrets

Collars that we are presently using are considerably more fragile than their predecessors and are intentionally designed to lack durability. Most black-footed ferrets (*Mustela nigripes*) shed the collars within 2 months (often much sooner). Use of more durable collars seems to increase the risk of neck sores. Presently, collars 1 cm wide are made of 100 percent wool, folded into three layers and sewn with 100 percent cotton thread. The edges are not bound, so the wool will fray rapidly. After sewing the wool into long strips of uncut collars, we prestretch the material. It is soaked in water and hung to dry with a 200-g weight clamped to the lower end. Collars are then cut to 15–18 cm lengths. To attach a collar to the transmitter unit, both are inserted into a 2.5-cm length of Teflon® heat-shrink tubing (1.25 cm diameter), and a heat gun (or other heat source such as a gas stove or propane torch) is used to shrink the tubing. Overheating the transmitter packages can cause malfunctions. High temperature for a short duration works better than less heat applied for longer times. The object is to heat the tubing without overheating the transmitter and battery. After shrinking the tubing, the package is cooled rapidly by wrapping it in a cool, wet sponge. Equipment and supplies needed to attach these collars to ferrets include scissors, a hemostat clamp, contact cement, a telemetry receiver, and a hair dryer. Mustelids characteristically have little neck constriction, making exact collar fit important. The attachment procedure for black-footed ferrets may be accomplished in the following steps:

1. Remove the magnet and check transmitter operation.
2. Restrain ferrets with a light dose of ketamine/diazepam (about 17–20 mg per kg of body weight) for this noninvasive procedure (Thorne and others, 1985). Recently, we have been using isoflurane gas anesthesia, which is more controllable (Biggins, Godbey, Matchett, and others, this volume). New innovations in gas anesthesia (e.g., sevoflurane; Gaynor and others, 1997) have additional advantages but require different vaporizers. The U.S. Fish and Wildlife Service requires ferret handlers to be trained in anesthesia and handling procedures.
3. As soon as the animal is tranquil enough to handle, make a trial fit of the collar and mark the length needed, allowing about 1-cm overlap of ends. Mark the area of overlap that will be glued, but do not trim excess from the long end of the collar until later. The extra length makes it easier to fit on the animal and can be trimmed at the end of the process.
4. Coat the inside of one end and the outside of the other end with contact cement. We use the Weldwood® (DAP® Products, Inc., Baltimore, Md.) version that has a toluene solvent, which seems to work better than the versions with other solvents. The glue-drying process takes 3–10 minutes. A hair dryer speeds drying. The first coat of cement normally penetrates the wool. Unless the glue is quite thick, the first coat must be dried completely and a second coat applied and dried until tacky.
5. Wrap the collar around the animal's neck and press a tiny portion of the glued strip together lightly. This process allows a final check for snugness before the final gluing is done. Collar fit is critical; it should be snug but not tight. The collar should rotate fairly easily around the neck. Also, a small closed hemostat or small scissors should slide easily between the neck and collar, but if you can insert your little finger, the collar is probably too loose.
6. If the fit seems satisfactory, press the glued ends together firmly. Use the hemostat to clamp the ends, repeatedly clamping and releasing until the entire overlap area has been pressed together firmly. Trim excess wool from the long end of the collar. We know of only one occasion when the glue joint failed, and that was when a technician did not realize that he had to let the glue dry before pressing the ends together. In fact, we have not been able to separate the final joint by pulling the ends apart—the material always tears. It may even be difficult to separate the ends during the trial fitting if they have made too much contact.

Postrelease Movements and Survival of Adult and Young Black-footed Ferrets

By Dean E. Biggins,[1] Jerry L. Godbey,[1] Travis M. Livieri,[2] Marc R. Matchett,[3] and Brent D. Bibles[4]

Abstract

A successful captive breeding program for highly endangered black-footed ferrets (*Mustela nigripes*) has resulted in surplus animals that have been released at multiple sites since 1991. Because reproductive output of captive ferrets declines after several years, many adult ferrets must be removed from captive breeding facilities annually to keep total production high. Adults are routinely released, with young-of-the-year, on prairie dog (*Cynomys* spp.) colonies. We evaluated postrelease movements and survival rates for 94 radio-tagged young and adult ferrets. Radio-tagged adult ferrets made longer movements than young ferrets during the night of release and had significantly lower survival rates for the first 14 days. Coyotes (*Canis latrans*) caused the largest number of ferret losses. A larger data set of 623 ferrets represented adults and young that were individually marked with passive integrated transponders but were not radio tagged. Minimum survival rates, calculated primarily from ferrets detected during spotlight searches and identified with tag readers, again were significantly lower for adults than for young ferrets at 30 days postrelease (10.1 percent and 45.5 percent survival, respectively) and at 150 days postrelease (5.7 percent and 25.9 percent). Assessment of known survival time by using linear modeling demonstrated a significant interaction between age and sex, with greater disparity between adults and kits for females than for males. Postrelease survival of adult ferrets might be increased if animals were given earlier and longer exposure to the quasi-natural environments of preconditioning pens.

Keywords: age, behavior, mortality, *Mustela nigripes*, predation, radio telemetry

Introduction

Black-footed ferrets (*Mustela nigripes*) nearly became extinct when diseases invaded the last known free-ranging population near Meeteetse, Wyo., in 1985 (Lockhart and others, this volume). A rescue effort resulted in a captive population that has provided ferrets for reintroduction since 1991. The mean life expectancy of free-ranging black-footed ferrets in the ancestral Meeteetse population was about 0.9 years (calculated by using the negative reciprocal of the natural log of 0.34, an annual survival rate estimated by Forrest and others, 1988). With such a short average life expectancy, natural selection may have applied little pressure for sustained productivity in older age classes of ferrets. In captivity, productivity declines rapidly after ferrets are only a few years old (Williams and others, 1991). Efficient management of the captive breeding program thus involves relatively rapid rotation of animals (Marinari and Kreeger, this volume). Older animals are placed in zoos for exhibit and used for research, but the supply of such animals exceeds the demand. Adult ferrets are routinely released at reintroduction sites, a practice that has been criticized. Although both young and adult ferrets have been released at several sites, their postrelease movements and survival have not been compared. Marking of animals, spotlight searches, and identification of surviving ferrets are tools routinely used for monitoring at release sites (Biggins, Godbey, Matchett, and others, this volume), providing useful multiyear data sets. In certain years, more intensive radio-telemetry studies (Biggins, Godbey, Miller, and Hanebury, this volume) were directed at testing hypotheses regarding prerelease experience and rearing methods. Cumulative data from these former efforts provide the opportunity to contrast the movements and survival of released adult and young ferrets.

Methods

Stratification Based on Rearing and Prerelease Experience

Rearing conditions and prerelease experience have profound effects on behaviors of young ferrets (Miller and

others, 1990a,b; Vargas, 1994; Biggins and others, 1999; Biggins, 2000), ultimately influencing postrelease survival rates (Biggins and others, 1998). Released adult (age at release >1 year) black-footed ferrets reported herein were given experience in outdoor pens, including living in natural burrows and killing prairie dogs, for 1–4 months prior to release. Former experimental designs that focused on testing effects of rearing on young ferrets (kits), however, involved more categories of preconditioning and more carefully controlled environments (Biggins and others, 1998). Those experimental designs encompassed most of the radio-tagged kits used in the following analyses but only a portion of the released kits that were not telemetrically monitored. Because early experiments indicated that cage-reared kits were dramatically different in several respects from their counterparts with experience in pens (Biggins and others, 1998, 1999), we did not include cage-reared kits in any of our analyses (telemetry or recapture). We also excluded kits that were born in pens or transferred into pens at the natal facility at an early age (<60 days) with their dams (the PENRES category of Biggins and others, 1998) from the telemetric data set. For a large number of kits that were not part of the early experiments, preconditioning was much more variable. Thus, our capture-recapture analyses encompassed a more broadly defined "preconditioned" group of kits that ranged from those placed in pens prior to 60 days of age with dams to those shipped after 90 days of age, without accompanying adults, from their original breeding facility to pens at other facilities or to remote pens near reintroduction sites.

In summary, we used two types of data to examine the influence of age of ferrets on their movements and survival. Radio telemetry provided information on cumulative movements, dispersal, minimum survival rates, and causes of mortality. A larger sample of ferrets that were individually marked (including those that were radio tagged) allowed additional estimates of survival via mark-recapture methods.

Radio Telemetry

We radio collared 137 black-footed ferrets with 5-g transmitter packages attached to 100 percent wool collars with Teflon® (DuPont, Wilmington, Del.) heat-shrink tubing (the latter to resist mud accumulation). Radio-tagged ferrets were released on Gunnison's prairie dog (*Cynomys gunnisoni*) habitat in the Aubrey Valley of northern Arizona and on black-tailed prairie dog (*C. ludovicianus*) habitat at UL Bend National Wildlife Refuge in Montana and the Burns Basin portion of Badlands National Park, S. Dak.

Transmitters, with their 20-cm whip antennas, provided a pulsed signal (pulse interval = 1.5 seconds; pulse width = 20 milliseconds) of about -14 dB, with battery life of about 45 days. Radio location was accomplished via triangulation from fixed stations fitted with paired, 11-element Yagi antennas on rotating masts (Biggins and others, 1999; Biggins, Godbey, Miller, and Hanebury, this volume). We tested accuracy of stations by comparing station-derived azimuths with true azimuths to beacon transmitters. We used standard deviations of the differences between such pairs in confidence intervals to predict the accuracy of future azimuths and the areas and diagonals of error quadrangles associated with positional "fixes" (White and Garrot, 1990). An initial test for each station provided data for evaluating bias patterns and developing formulas for adjustment, and a second set of readings was used to calculate residual variation after bearings were adjusted (Biggins and others, 1999). We referenced stations prior to each tracking session (Biggins, Godbey, Miller, and Hanebury, this volume) using from 2 to 5 beacon transmitters. For these analyses, we used radio-telemetry data for the first 14 days postrelease (although tracking extended over a longer period at some sites). We used the computer program TRITEL to process azimuth data (Biggins, Godbey, Miller, and Hanebury, this volume); processing included adjustments for referencing and bias and calculation of coordinates and error estimates for each fix. Hand-held tracking equipment assisted us in recovery of lost collars and dead ferrets.

For comparisons of age groups, we used the subset of the 137 instrumented animals (excluding 20 PENRES kits and 23 cage-reared kits as defined above) that included 38 adults and 56 "preconditioned" kits (table 1). We screened data for gross radio-tracking and data entry errors by using the systematic approach of Breck and Biggins (1997). We then summarized cumulative movements between consecutive fixes and dispersal from the release site for each ferret and night. We analyzed cumulative movements by using a repeated measures multivariate general linear model (MGLM) with average area of error quadrangle, sex, and site as covariates. We used square root transformations of the response variables to improve normality and homoscedasticity of residual variation. We assumed that the area of an error quadrangle would account for a portion of the variation in the cumulative movement of a ferret and retained this measure of tracking error as a control variable in statistical models regardless of its significance. Because dispersal is defined as movement away from the release site and increased distance from tracking stations causes larger error quadrangles, tracking error was not considered in statistical evaluations of dispersal, but sex and site were included as covariates.

Causes of mortality were determined by evidence at recovery sites (e.g., tracks, scat, fur, feathers, digging), condition of carcass (e.g., hemorrhage, bite wounds, saliva), and radio-tracking data (patterns of fixes and activity, timing of death). We assessed risk-adjusted survival rates by relating deaths (table 1) to days of telemetric monitoring (Heisey and Fuller, 1985). An estimate of maximum survival resulted from considering only known deaths. Counts of animals known dead underestimate mortality rates because not all dead animals are detectable (underground deaths due to badgers, for example, may be underestimated) and because some proportion of loss of telemetric contact with animals is due to transmitter damage inflicted during predation. (We have recovered a few badly damaged transmitters that were barely functional and assume that others became nonfunctional.) We thus

Table 1. Numbers of preconditioned adult and young radio-tagged black-footed ferrets (*Mustela nigripes*) released in Arizona, South Dakota, and Montana during 1994–96.

estimated a minimum survival rate by summing the number of ferrets that were lost from telemetric contact and the number known to be dead. If an animal was found alive at a later date during spotlight surveys, it was considered alive for the first 14 days (even if telemetric contact was lost and it would have been listed as missing). If an animal died or became missing after 14 days, it was treated as alive for the first 14 days. Our multivariate general model had eight parameters (two ages, four site/year combinations). In this survival analysis, we compared models and their nested submodels using likelihood ratio tests.

Mark-recapture

The data set for this portion of the study (table 2) included all black-footed ferrets released during 1994–2000 at Badlands National Park and Conata Basin in South Dakota, ferrets released during 1994–97 at UL Bend in Montana (including the radio-tagged individuals mentioned above), and ferrets released at the Coyote Basin site of Utah and adjacent Colorado. Of the 623 ferrets released (table 2), 325 were males and 298 were females. All released ferrets were individually marked, mostly with passive integrated transponder (PIT) tags subcutaneously implanted over the shoulder. A second PIT tag often was implanted over the hip (Biggins, Godbey, Matchett, and others, this volume). "Recapture" (in this case, mostly reading the transponder) was accomplished via spotlight surveys to locate the ferrets (Campbell and others, 1985; Biggins and others, 1998) followed by placement of a transponder reader at the occupied burrow to automatically read and retain the chip number (Biggins, Godbey, Matchett, and others, this volume). The first survey at each site usually was conducted about 1 month postrelease, with additional surveys conducted prior to the breeding season (in some cases) and postwhelping (most sites). Intensity of these survey efforts varied among sites and years due to availability of resources.

Counts of surviving animals at 30 and 150 days postrelease were based on the same released ferrets and thus cannot be considered statistically independent. Also, the 71 radio-tagged ferrets in South Dakota and Montana are a subset of the 623 animals considered in the capture-recapture analyses. We chose to maintain separate 30-day and 150-day mark-recapture analyses (rather than a more complex single model) because of sample size differences and unequal time intervals between surveys and because survival estimates for these time periods can be compared with similar estimates reported elsewhere for ferrets. Survival was considered cumulatively; ferrets found alive at 150 days (or later) were counted as alive on day 30 even if they were not found in the earlier period. Because spotlight sessions of equal intensity were not replicated systematically at all sites (or even among days within sites), we did not attempt traditional capture-recapture modeling where capture rates and survival rates could be estimated separately. Our rates, therefore, must be considered as minimum survival (the products of capture rate and survival rate), recognizing that not all ferrets were likely to have been located at any site. Interpretation of the comparisons between adults and kits thus requires the assumption that each age class (within each site) was equally detectable by spotlighting, an assumption that we believe is reasonable. We estimated survival rates from spotlight searches by using an iterative numerical optimization procedure (program SURVIV; White, 1983). The general model included 12 parameters (3 sites, 2 sexes, 2 ages).

Elapsed time from release until the last detection for each ferret also was calculated. Time intervals between releases and the first spotlight survey and between subsequent spotlight surveys varied considerably among sites and years, from a single survey per year to nearly continuous surveys. Variability in survey timing tended to distribute this measure of survival in a continuous (but skewed) form, and square root transformation improved its suitability for use as a continuous response variable in a MGLM analysis, allowing additional assessment of the potential interaction between age and sex.

We recognize that detectability of ferrets via spotlight searches is likely to differ among sites due to differences in access, vegetative cover, topography, intensity of effort, and other variables. Thus, we consider multivariate modeling, with a site variable included, as critically important. Potential differences in search efficiency also preclude any conclusions regarding differences in survival among sites.

An important consideration in our experimental design, for both telemetric and capture-recapture data, was to maintain a reasonable balance of treatments within sites (and within years, with one exception). Other priorities always affected allocations of animals, but, to avoid serious confounding during interpretation of results, we did not allow any cell of the design to be empty. Thus, groups of released ferrets that did not contain adults and kits of both sexes were excluded from analyses. The exception to this general rule occurred within the telemetry data set, where adult ferrets were released in Badlands National Park in spring, and kits were released at that site during fall of the following year.

We followed the principle of parsimony in evaluating competing statistical models (Lebreton and others, 1992), attempting to reduce general models to simpler submodels by eliminating variables that appeared to have low explanatory power. For capture-recapture analysis within program SURVIV, reduced models were evaluated by likelihood ratio tests and Akaike's Information Criterion (AIC) (Anderson and Burnham, 1994). For MGLM evaluations and likelihood ratio testing, *P* values >0.10 were deemed sufficient for eliminating variables from models.

Results

Radio Telemetry

Of the 137 radio-tagged ferrets that were released, 59 were considered lost to the population, mostly as a result of predation (fig. 1). Coyotes (*Canis latrans*) caused the most losses, but prior to its removal a great horned owl (*Bubo virginianus*) had a substantial impact at one site in South Dakota. American badgers (*Taxidea taxus*) were common on prairie dog colonies where ferrets were released, but they killed ferrets only occasionally. The species of predator responsible for ferret deaths could not always be determined, however, resulting in some classifications of "unknown predator" or "unknown raptor" (fig. 1).

Multivariate repeated measures analysis of square root transformed cumulative movements for ferrets that were monitored for at least three nights yielded a significant interaction between night postrelease and age group ($F_{2,59} = 7.407$, $P = 0.001$) with a model that included age, site, and mean area of error quadrangle (per animal over three nights). Thus, the pattern of change in nightly movements of kits and adults was significantly different over the first three nights postrelease (fig. 2; nontransformed data). Tracking error (area of error quadrangle) contributed significantly to the variation in movements ($F_{1,60} = 5.620$, $P = 0.021$), underscoring the importance of a variable to account for this source of "nuisance" variation

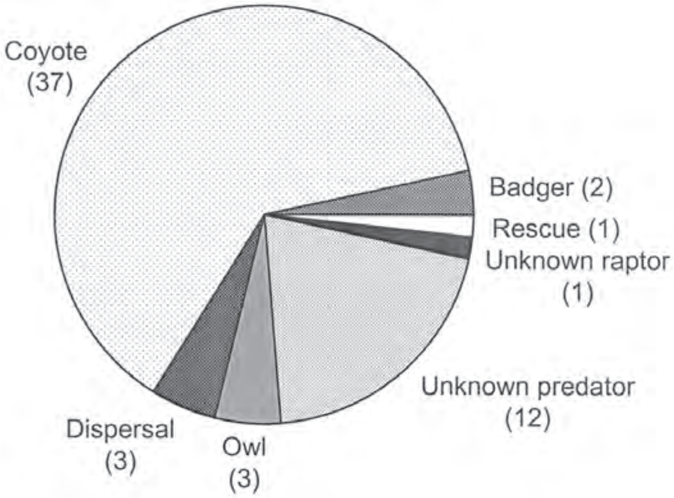

Figure 1. Causes of loss for 59 of 137 radio-tagged black-footed ferrets (*Mustela nigripes*) released in Montana, South Dakota, and Arizona during 1994–96. "Rescued" ferrets are those that we assume would have been lost without our intervention (translocation or treatment for injuries). "Unknown predator" and "Unknown raptor" are general categories for which the species of predator could not be identified.

in models of movement. Nightly movements also appeared to be different at different sites ($F_{3,60} = 3.693$, $P = 0.017$).

The relatively long movements of adult ferrets on the night of release suggested that they might have “bolted” from the release site (i.e., dispersed rapidly away from the point of release), but a repeated measures analysis of dispersal during the first three nights did not support that contention (fig. 3). Although there was a significant tendency for ferrets to drift away from their release sites over the first several nights ($F_{2,58} = 8.860$, $P < 0.001$), the pattern of dispersal was not significantly different for kits and adults ($F_{2,58} = 1.107$, $P = 0.337$). Thus, “bolting” is not an appropriate description of the behaviors of adults. They simply moved more than kits during their first night but did not tend to leave the area of release any differently than did kits. In this analysis of dispersal, there was no evidence of differences among sites ($F_{3,59} = 1.209$, $P = 0.315$).

Survival of radio-tagged adults appeared to differ significantly from survival of radio-tagged kits. For the estimates of maximum survival, generated by considering only known deaths (fig. 4), likelihood ratio testing did not support reduction in number of parameters by pooling sites ($X^2 = 45.4$, $df = 6$, $P < 0.001$) or ages ($X^2 = 29.3$, $df = 4$, $P < 0.001$). The same was true for the estimates of minimum survival, using ferrets known to be dead plus those with whom radio contact was lost during the 14-day tracking period (sites, $X^2 = 38.6$, $df = 6$, $P < 0.001$; ages, $X^2 = 38.7$, $df = 4$, $P < 0.001$). There was thus a similar overall pattern of differences between survival rates of adults and kits, regardless of the method of categorizing mortalities (fig. 5). If about one-third of the missing animals actually died when their signals were lost, the overall projected survival rates for 30 days postrelease would have been 42 percent for kits and 11 percent for adults. The curves vary among sites and with methods, but kit survival was higher than adult survival within each comparison.

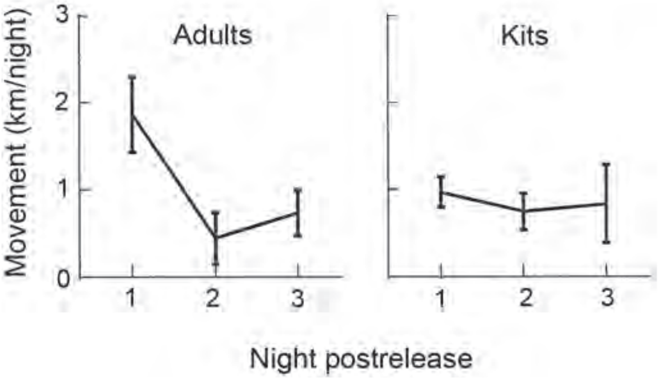

Figure 2. Mean cumulative nightly movements for adult and young radio-tagged black-footed ferrets (*Mustela nigripes*) during the first three nights postrelease (mean ± SE).

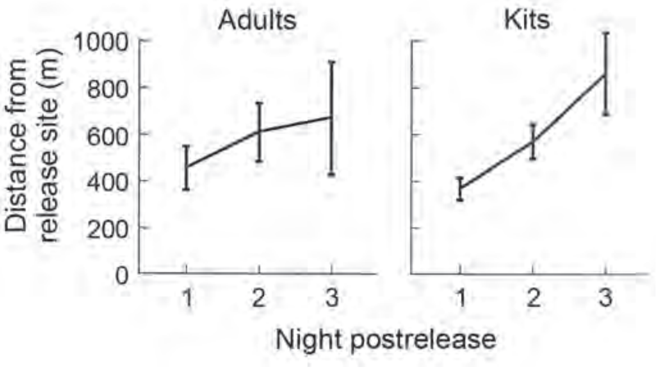

Figure 3. Nightly maximum displacement from release sites for young and adult radio-tagged black-footed ferrets (*Mustela nigripes*) during the first three nights postrelease (mean ± SE).

Mark-recapture

The preferred model of minimum survival from the spotlight search data was the general model for both the short-term (30-day) (table 3) and the long-term (150-day) assessment (table 4), although the evidence for distinction between the sexes was strongest in the long-term evaluation. Minimum survival rates were higher for kits than for adults in 11 of the 12 pairs of estimates for the two time periods, averaging 45.5 percent (kits) and 9.8 percent (adults) at 30 days (fig. 6) and 25.9 percent (kits) and 5.7 percent (adults) at 150 days (fig. 7). Minimum survival rates tended to be higher for females

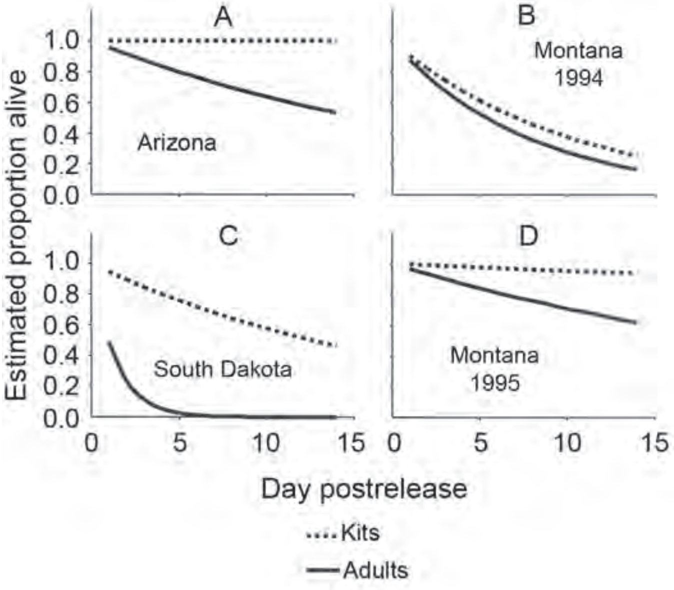

Figure 4. Postrelease survival curves for preconditioned adult and young radio-tagged black-footed ferrets (*Mustela nigripes*) extrapolated from daily survival rates (assuming a constant hazard rate for the 14-day period of the experiment and using only known deaths).

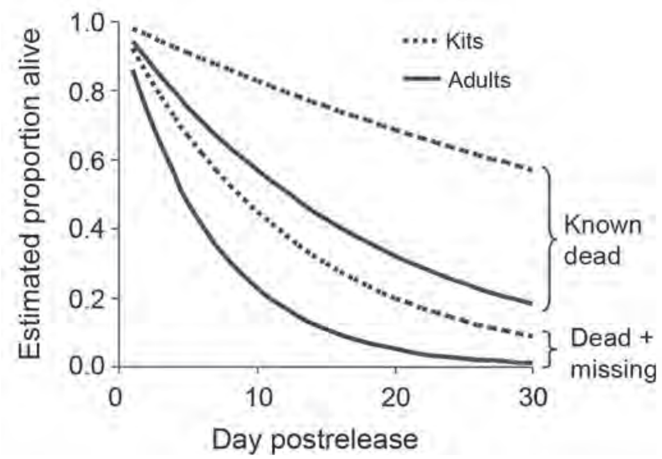

Figure 5. Bracketed high and low survival of adult and young radio-tagged black-footed ferrets (*Mustela nigripes*) for the first 30 days postrelease, generated by using only ferrets known to be dead (high) and known deaths plus ferrets lost to radio contact (low). Curves were extrapolated from daily survival rate estimates assuming a constant hazard rate for the period.

than for males (figs. 6 and 7). For kits, the disparity between sex-specific survival rates was proportionately greater for the long-term estimates (males, 18.9 percent; females, 35.7 percent) than for the short-term estimates (males, 39.9 percent; females, 53.4 percent). Moreover, there seemed to be different patterns for adults and kits within the two genders for both the short-term and long-term data sets. That potential interaction warranted closer examination.

General linear modeling of elapsed time between release and the last detection demonstrated a significant interaction between sex and age ($F_{1,617} = 5.522$, $P = 0.011$); known survival times tended to be shorter for adults than for kits (fig. 8). We retested the sexes separately because of the interaction. As implied by the pairs of graphs, female kits survived significantly longer than did adult females ($F_{1,294} = 40.250$, $P < 0.001$), but the difference between the age groups was only marginally significant for males ($F_{1,294} = 3.387$, $P = 0.067$).

Discussion

Radio Telemetry

There is a potential bias built into assessments of ferret movements. Repeated measures analyses, particularly, require complete sets of multiple measures on single animals; any ferret that lacked a measure of movement for any of the first three nights postrelease (fig. 2), for example, was excluded from our analysis. Thus, ferrets that tend to engage in risky behaviors tend to be removed (by death) at higher rates from the sample, likely causing movements to be generally underestimated, and (more seriously for this kind of experiment) the effect may be greater on some treatment groups than on others. If we assume that there is a positive correlation between movement and mortality rate (Biggins and others, 1998), we likely underestimate movement differences between groups. We have been able to detect such differences, but more subtle disparities between treatment groups may remain unnoticed. Statistical models that are not based on repeated measures also would be affected, but more flexible rules for handling those data should result in a less dramatic influence. Although early deaths of individuals having presumably lower fitness may cause a shift in representation of animals, their movements before they were killed remain in data sets used for statistical analyses other than repeated measures.

Survival of radio-tagged kits differed more dramatically from adults at the Burns Basin, S. Dak., release site than at any other site (fig. 4). Although the same release site was used for both kits and adults, and they were radio tracked from the same system, Burns Basin was the only site where adults and kits were not released at the same time. It is possible that the differences there were due to year or season.

The different appearance of survival curves among sites generated from telemetric data (fig. 4) should not be construed as being linked to the species of prairie dog or other site-specific conditions. Efficiency of radio tracking is likely responsible for much of the variation. The Aubrey Valley site

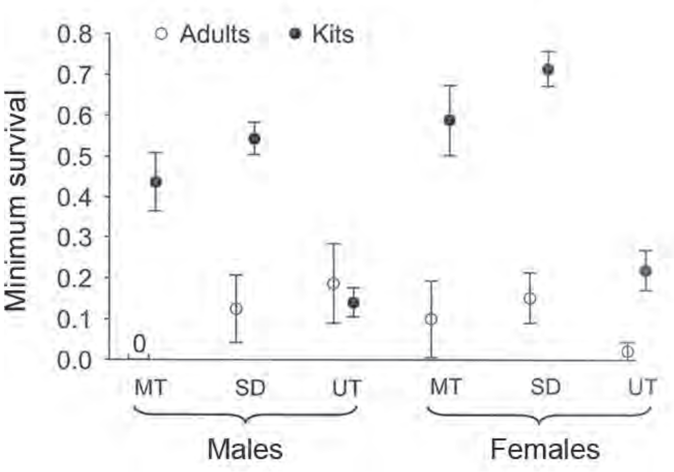

Figure 6. Minimum short-term (30-day) survival of adult and young preconditioned black-footed ferrets (*Mustela nigripes*) released onto prairie dog colonies (*Cynomys* spp.) in Montana (MT), South Dakota (SD), and Utah (UT) during 1994-2001 (mean ± SE).

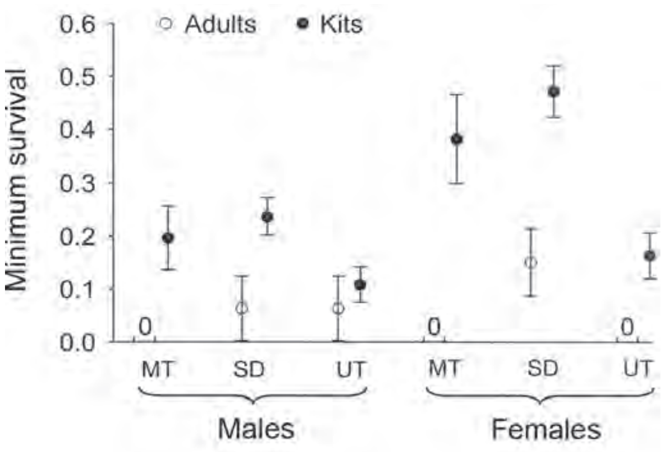

Figure 7. Minimum long-term (150-day) survival of adult and young preconditioned black-footed ferrets (*Mustela nigripes*) released onto prairie dog (*Cynomys* spp.) colonies in Montana (MT), South Dakota (SD), and Utah (UT) during 1994–2001 (mean ± SE).

in Arizona, in particular, presented a challenge. Wide spacing between stations was necessary to achieve appropriate coverage of the site, but contact was lost with many animals because of the long distances over which they were tracked. The result may have been a reduced probability of finding dead ferrets, and such known mortalities were the basis for the curves generated. In contrast, Burns Basin in South Dakota provided much better radio-tracking conditions that favored finding cases of mortality (stations were on high points). Overall, highest rates of survival for kits have been in South Dakota as exemplified by our mark-recapture data set. Site characteristics have influenced the efficiency of both spotlight searches and radio telemetry, causing us to adopt experimental designs that compare two or more treatments within sites, to replicate the design over multiple years and sites to achieve adequate sample sizes, and to exercise caution in interpreting results from multiple sites. We might have remained more suspicious about the possible ramifications of our design and potential for confounding without the corroborating results produced by the much larger sample sizes of released ferrets in the mark-recapture portion of the study.

Mark-recapture

Differences between survival rates of males and females were not detected previously (Biggins and others, 1998) in a much smaller data set of 262 ferrets (64 of those animals were included in our present data), although there was speculation that the expected trend toward lower male survival in longer-term data was developing and would be validated with larger sample sizes. Failure to detect such a difference in our data would indeed have been troubling given the male bias in the numbers of animals released (325 males:298 females) and the female-biased composition of free-ranging ferret populations (Forrest and others, 1988). For kits only (comparable to the analysis of Biggins and others, 1998), a gender effect

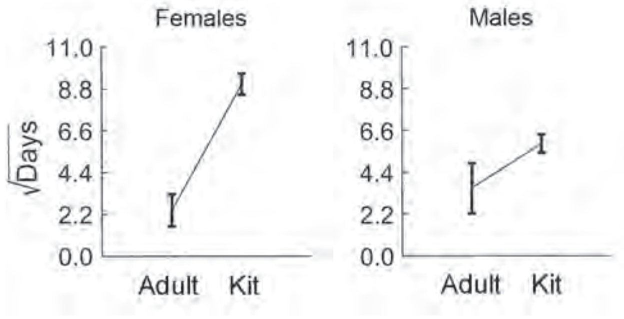

Figure 8. Number of days of known survival for marked adult and young black-footed ferrets (*Mustela nigripes*) calculated using detections from spotlight searches, snow-track searches, and radio telemetry (mean ± SE).

in our data was detectable for both the short-term and long-term evaluations, but the effect became more dramatic over time. Perhaps males became increasingly territorial during the approach of breeding season.

The significant interaction between age and sex classes has potentially nontrivial management ramifications. The interaction may be explained if older age tends to confer greater social status to males than to females, creating a potential problem if adult males have poor long-term survival skills compared to preconditioned male kits. Some older males may be able to competitively exclude younger males, subjecting the latter to temporarily higher mortality. The competition could result in lower overall survival rates for young males without any compensatory increase in long-term survival rates for adult males. If younger males are lost during transitory social interactions with dominant older males, and the older males tend to be lost before breeding season, a shortage of males could result. This phenomenon could occur with concurrent releases of adult and young males, or during releases to augment populations.

General Considerations

Daily survival rates estimated from the 14-day radio-telemetry data set for 94 radio-tagged ferrets seemed reasonably predictive of the 30-day survival rates derived from mark-recapture data on the larger data set of 623 animals. The telemetrically originated survival rates of 42 percent for kits and 11 percent for adults are similar to the overall capture-recapture survival rates of 46 percent for kits and 10 percent for adults. Such comparisons are speculative, however, because of the differing methods and attendant assumptions. First, it is only a reasonable guess to assume that one-third of cases of lost radio contact were due to death of the ferret. Second, the 14-day survival rates were produced under the assumption of a constant hazard rate, an assumption that was repeated to produce the 30-day extrapolation. Hazard rates likely decline postrelease as ferrets with lower fitness are culled and as ferrets learn about their new environment. Over short time spans, the flat hazard rate seems reasonable. Applying a rate generated during the first 2 weeks postrelease to long time spans would be ill-advised. Indeed, our spotlight detections at 150 days (25.9 percent of kits released and 5.7 percent of adults released) were much higher than the respective 3.0 percent and 0.0 percent expectations of the extrapolated daily rates from the first 14 days of radio-tracking data. Third, the mark-recapture estimates are for minimum survival; the actual rate must be somewhat higher assuming we do not count all ferrets present. Finally, the average rates discussed here ignore the implications of statistical modeling, which suggested that rates should be separately estimated for sexes and sites.

Postrelease survival of adult black-footed ferrets might be improved if all young were reared in pens whether they were immediately destined for release or for the captive breeding program. A type of phase-specific learning (Davey, 1989) in which an animal may “imprint” on features of its habitat during a critical period of development has not been investigated for ferrets, but differences in postrelease survival and movements of ferrets as a result of rearing history (Vargas, 1994; Biggins and others, 1998, 1999) arouse suspicion. Even if imprinting is not involved, cultural transmission of important behaviors may be enhanced by a natural environment (Biggins, 2000). Ensuring that each generation has early learning experience in a quasi-natural environment has several potential benefits. Whether or not all kits are raised in pens, increasing the amount of time they spend in outdoor pens could be advantageous. Females that have spent three summers rearing young in the burrows of outdoor pens may make better candidates for release than females without such experience. Perhaps males could be kept in the outdoor pens during much of the remainder of the year, a practice that may accrue additional benefits in reproductive performance (D. Kwiatkowski, oral commun., 1991). Additional investigations of these types of variables might lead to enhanced postrelease survival of captive-reared ferrets.
